Abstract. The coordination language Paradigm allows for a flexible and orthogonal modeling of interprocess relationships at the architectural level. It is shown how dynamic system adaptation can be captured in Paradigm by means of a special evolution component and associated evolution coordination scheme. The component, called McPal, drives the migration following a just-in-time strategy in its own view of the system, independent of other coordination relations. During migration, dynamic consistency between components remains assured, even for mixtures of old, intermediate and new behaviour. A restricted scheme of McPal that supports various forms of self-adaptation is presented. A simple but generic example of a scheduler and workers illustrates onthe-fly updating of coordination and run-time adaptation of scheduling policies using McPal.

Keywords: evolution on-the-fly, dynamic consistency, self-adaptation, migration, software architecture, Paradigm

1 Introduction

Dynamic aspects of coordination arise naturally when considering evolution onthe-fly of systems at the architectural level. Here, evolution on-the-fly, such as dynamic software updating, is in contrast to other unanticipated system adaptation where components are first put to a halt, subsequently supplied with new behaviour, and finally restarted, likely with their state restored. In the setting here, the execution of the system should continue as much as possible. While running, the system will adapt itself and evolve into a new one via a number of migration steps, taken by the different components in a well-coordinated fashion.

The system architectures addressed in this paper are given as Paradigm models. Paradigm is a coordination language distinguishing detailed and global behaviour of processes (see [8, 12]). Coordination is achieved, by properly connecting the detailed and global views via so-called consistency rules. These rules relate detailed transitions between states of a process in a manager role to global change of subprocess constraints of other processes in an employee role. In Paradigm, separate coordination solutions for multiple collaborations can be relatively easily combined into one single architecture.

The paper's main contribution lies in showing how a specific component, called McPal –abbreviating Managing changing Processes ad libitum (or at

leisure)— allows for modifying the dynamics of the system on-the-fly, while all components remain in execution in a dynamically consistent manner. The important intuition here is, a process within a model is viewed as a subprocess of an unknown larger process. As long as this subprocess constraint is valid, it is irrelevant whether the remainder of that process is known or not. This allows for defining new fragments of the process in a lazy manner, by modeling them just in time. After having such new fragments defined in a suitable manner, McPal can, on the basis of newly added dynamics, start to coordinate global level behaviour, eventually leading into a new evolutionary phase for each component. Thereby, the Paradigm notions guarantee enduring consistency between the components' behaviours before, during and after the migration, even for mixtures of old, intermediate and new behaviours.

To keep our explanation clear and sufficiently brief, we restrict this paper to a relatively simple form of McPal, not changing its own behaviour. This way, an evolution pattern for Paradigm models emerges, illustrated by an example of a scheduler and workers involved in different evolution scenarios. The starting point is a scheduler that excludes almost all overlapping of activity of the workers. As a first illustration, the coordination evolves to a situation where this restriction is significantly alleviated, allowing for more parallelism amongst the workers. A second illustration of the evolution pattern focuses on the scheduler, that migrates from a non-deterministic selection of workers to a round-robin selection policy.

In view of the above, the remainder of the paper has the following structure. Section 2 briefly describes Paradigm and introduces a small coordination example model. First, the model is extended in Section 3 with McPal for coordinating future self-adaptation of the model. Sections 4 and 5 present two different evolutionary continuations, one for reducing the critical sections, the other for changing the scheduling policy of workers. Both evolutionary changes are onthe-fly. Finally, Section 6 gives conclusions and discusses both related work and future research.

2 Paradigm

This section provides a very brief introduction to the coordination language Paradigm by means of a small example. The example serves two purposes, of illustrating the notions explained and of preparing the evolution to be addressed later. For more detailed explanation, including formal operational semantics, see e.g. [8,12,11]. Consider the following coordination situation. A scheduler is coordinating the activities of three workers. The workers are performing the same life-cycle simultaneously: alternating between not working and working. A worker is idle in the state free. The activity working actually consists of four smaller consecutive activities: nonCrit, pre, crit and post. The scheduler is coordinating their working. For the moment, the scheduler allows at most one worker outside of free and nonCrit. The activities of the workers and of the scheduler can be described by a process or state transition diagram (STD).

In general, a process or STD S is a triple $\langle \mathtt{ST}, \mathtt{AC}, \mathtt{TS} \rangle$, with \mathtt{ST} the set of states, with \mathtt{AC} the set of actions or labels, and with $\mathtt{TS} \subseteq \mathtt{ST} \times \mathtt{AC} \times \mathtt{ST}$ the set of transitions. We write $x \xrightarrow{a} x'$ in case $(x, a, x') \in \mathtt{TS}$, or even $x \to x'$ if the precise action is irrelevant.

Figure 1 visualizes the processes of a worker and of the scheduler as directed graphs: transitions as edges and states as nodes. Activities have been mapped

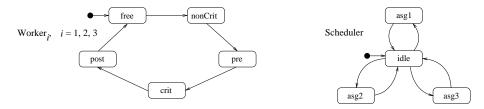

Fig. 1. Processes Worker $_i$ and Scheduler

to states (as time spent for an activity coincides with a sojourn in a state); actions have been left empty. Each worker process, starts in state free, its nonworking activity. After state free, Worker $_i$ continues to work: in nonCrit he does non-critical work, in pre he prepares the critical activity, in crit he does his critical work and in post he does its follow-up. Thereby he finishes working and continues in free with non-working. Process Scheduler starts in state idle where he does not allow any worker to do non-critical working. From state idle he can go non-deterministically to any of his states asg_i , i=1,2,3, where he only allows Worker $_i$ to enter and leave states pre, crit and post for performing one full turn of critical activity.

The coordination exerted by the scheduler is formulated in terms of three global processes, each constituting a coarse-grained view of a worker process. Global processes are built from subprocesses and traps of the process it corresponds to. In general, a subprocess of a process $S = \langle \mathtt{ST}, \mathtt{AC}, \mathtt{TS} \rangle$ is a process $\langle \mathtt{st}, \mathtt{ac}, \mathtt{ts} \rangle$ such that $\mathtt{st} \subseteq \mathtt{ST}, \mathtt{ac} \subseteq \mathtt{AC}$ and $\mathtt{ts} \subseteq \{(x, a, x') \in \mathtt{TS} \mid x, x' \in \mathtt{st}, a \in \mathtt{ac}\}$. Furthermore, a trap θ of a subprocess $S = \langle \mathtt{st}, \mathtt{ac}, \mathtt{ts} \rangle$ is a non-empty set of states $\theta \subseteq \mathtt{st}$ such that $x \in \theta$ and $x \xrightarrow{a} x' \in \mathtt{ts}$ imply that $x' \in \theta$. If $\theta = \mathtt{st}$, the trap is called trivial. For the worker processes we model two subprocesses, viz. Free and Busy with their traps started and done visualized as polygons surrounding the states belonging to it. See the left part of Figure 2.

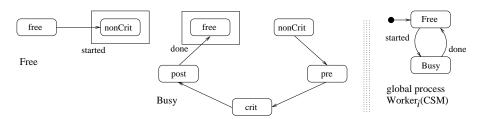

Fig. 2. Partition CSM and global worker process at the level of CSM

Subprocesses and traps are both constraints: a subprocess of a process is a constraint on the possible behaviours of the process, meant to be temporary and meant to be imposed from outside the process by a *manager*. In the example, as we shall see, the process Scheduler will be the manager. A trap of a subprocess is a constraint on the subprocess' state space –once entered the trap cannot be left–valid only for the time the subprocess constraint holds, and committed to from inside the process in its *employee* role. So, a trap indicates a final stage of a subprocess.

To build suitable dynamics from such constraints, two more notions are needed: partition and connecting trap. In general, a partition π of a process $P = \langle \mathtt{ST}, \mathtt{AC}, \mathtt{TS} \rangle$ is a collection $\{ (S_i, T_i) \mid i \in I \}$ of subprocesses $S_i = \langle \mathtt{st}_i, \mathtt{ac}_i, \mathtt{ts}_i \rangle$ of P, each with a set T_i of its traps. Furthermore, for two subprocesses $S = \langle \mathtt{st}, \mathtt{ac}, \mathtt{ts} \rangle$ and $S' = \langle \mathtt{st}', \mathtt{ac}', \mathtt{ts}' \rangle$ of a partition π , a trap θ of S is called a connecting trap from S to S', if the states, of S, belonging to the trap θ are states in S' as well, i.e. $\theta \subseteq \mathtt{st}'$. If such a connecting trap θ from S to S' exists, the triple (S, θ, S') is called a subprocess change or transfer. In Figure 2, the left part presents the elements of partition CSM (abbreviating critical section management) of a worker process, comprising the two subprocesses and the two traps. In this case, trap started of Free is connecting from Free to Busy as its state nonCrit belongs to Busy too. Similarly, trap done of Busy is connecting from Busy to Free as its state free belongs to Free too. A connecting trap provides a kind of overlap between two consecutive subprocess constraints.

On the basis of a partition π of a process P, we construct a new process, referred to as the global process at the level of partition π . This process is denoted by $P(\pi)$. Its states are the subprocesses from π , its actions are connecting traps from π and its transitions are the subprocess changes corresponding to these connecting traps. The one subprocess expressing the constraint valid at a certain moment, is referred to as the current subprocess of a partition at that moment. By construction, the current subprocess of a partition corresponds to the current state of the global process at the level of the partition. A process not being global, is referred to as detailed. Figure 2's right part presents the global process Worker_i(CSM), with its starting state Free chosen such that, as subprocess, it contains starting state free of process Worker_i. The process Worker_i(CSM) presents a behavioural view on the original Worker_i process; being less detailed than Worker_i, process Worker_i(CSM) is more coarse-grained, which is referred to as global in our terminology. Note that, a process can have multiple partitions, for each of which a global process exists.

Given a number of processes with associated partitions, so-called consistency rules relate detailed transitions between states of a manager process to global transfer between subprocesses of employee processes. (In this context, 'consistency' refers to the notions of dynamic consistency, horizontal or vertical, as proposed by Küster [14].) For a consistency rule to be applicable, one has to keep track of the current state of detailed as well as global processes. Any applicable consistency rule, no matter of what manager and partition, can be selected

for application. In general, a consistency rule has the format

$$P: s \xrightarrow{a} s' * P_1(\pi_1): S_1 \xrightarrow{\theta_1} S'_1, \dots, P_n(\pi_n): S_n \xrightarrow{\theta_n} S'_n. \tag{1}$$

In consistency rule (1), process P is the manager and process P_1 to P_n are the employees. Paradigm is restricted to having exactly one manager in a consistency rule. In case there are no employees, i.e. n=0, we simply write $P: s \xrightarrow{a} s'$. Note that the local transition of P in (1) does not refer to a partition. The requirement on P for the consistency rule to apply is that the transition $s \xrightarrow{a} s'$ is possible in every current subprocess of process P, with respect to the various partitions of P. The requirements on P_1 to P_n with respect to consistency rule (1) is that each process P_i in its partition π_i has S_i as the current subprocess and within this subprocess trap θ_i has been entered. After application of the consistency rule the current state of manager P becomes s', the current subprocesses of employees P_1 to P_n become S'_1 to S'_n , respectively. Because of the demand of traps θ_i being connecting for subprocesses S_i and S'_i , it does not matter in which detailed state the employees reside precisely. For each connecting trap, the whole of it is admitted in the new subprocess as a possible state to continue from.

For the scheduler process of our example, we provide the consistency rules

$$\begin{array}{ll} \texttt{Scheduler:idle} \rightarrow \texttt{asg}_i \ * \ \texttt{Worker}_i(\texttt{CSM}) \text{:} \ \texttt{Free} \overset{started}{\rightarrow} \texttt{Busy} \\ \texttt{Scheduler:asg}_i \rightarrow \texttt{idle} \ * \ \texttt{Worker}_i(\texttt{CSM}) \text{:} \ \texttt{Busy} \overset{done}{\rightarrow} \texttt{Free} \end{array}$$

The first consistency rule expresses that Scheduler may change its current state idle into asg,, provided the current subprocess constraint on Worker, is Free and the trap started has been entered, i.e. Worker, 's current state belongs to the trap started. If Scheduler changes its current state from idle to asg, indeed, then, according to the rule, global process $Worker_i(CSM)$ changes its current state from Free to Busy, or, put otherwise, the subprocess constraint of Worker, in partition CSM becomes Busy instead of Free. This is an example of horizontal dynamic consistency [14], as the rule couples behaviours from different components. Analogously, the second rule says, Scheduler may return from state asg_i to state idle, provided the current subprocess constraint on Worker_i is Busy and Worker,'s current state belongs to trap done. If Scheduler indeed changes its current state from asg, to idle, then also global process Worker, (CSM) changes its current state from Busy to Free. We see how both consistency rules couple one local scheduler transition to a (simultaneous) global Worker_i(CSM) transition. As Scheduler does not have a partition, it neither has any process at such a level, so Scheduler's state transitions are not restricted by any current subprocess constraint from such a global level.

The workers have no employees. Therefore, their consistency rules are simpler than for the scheduler, each rule containing one of $Worker_i$'s detailed transitions only.

 ${\tt Worker}_i{:}\, {\tt free} \longrightarrow {\tt nonCrit} \qquad {\tt Worker}_i{:}\, {\tt crit} \longrightarrow {\tt post}$ ${\tt Worker}_i{:}\, {\tt nonCrit} \longrightarrow {\tt pre} \qquad {\tt Worker}_i{:}\, {\tt post} \longrightarrow {\tt free}$

 ${\tt Worker}_i {:} {\tt pre} o {\tt crit}$

A Worker_i transition is possible only if it belongs to the current subprocess constraint of detailed process $Worker_i$ or, equivalently, to the current state of global process $Worker_i(CSM)$. This is an example of vertical behavioural consistency in the sense of [14] between a detailed process and the global processes at the levels of its partitions.

In addition to the consistency rule format of (1), one can also have a so-called *change clause*, a consistency rule used here solely for changing the total set of consistency rules, instead of a consistency rule prescribing subprocess changes. A change clause is formulated as

$$P: s \xrightarrow{a} s' * [var := expr]$$
 (2)

concerning a variable var, typically holding the list of consistency rules. It specifies that after application of the rule, process P has moved to state s' and the value of expr in s has been assigned to variable var. This way consistency rules can be added or deleted dynamically.

The initial configuration of a Paradigm model does not only comprise the starting states of the various detailed processes, but also those of the various global processes. Therefore, for every detailed process a starting state has to be specified, together with a subprocess to start from, for each of its partitions. Our example illustrates this as follows. The combined starting states are, grouped per detailed process and with i=1,2,3:

$$(Worker_i, Worker_i(CSM)): (free, Free), Scheduler: idle$$

Note, each detailed starting state belongs indeed to each current subprocess constraint for that particular detailed process. The consistency rules guarantee the following property to be invariant: each current state of a detailed process belongs for each partition of that process to the current subprocess.

In summary, the above is an example of a Paradigm model. In general, a Paradigm model is a collection of detailed processes and global processes at the level of their given partitions, together with a set of consistency rules and a combination of detailed and global starting states. Dynamics within such a model stem from subsequent application of consistency rules. Any change of constraint specified by the particular consistency rule applied, then yields a number of global process transitions, i.e. subprocess transfers.

3 Self-Adaptation and McPal

In this section we shall present a different model for the original coordination problem from the previous section. Apart from solving the same coordination problem, the model can modify itself and evolve, while remaining in execution, into another model, unknown in the beginning. For this we add the special process McPal. This McPal starts with not influencing the model as-is, nothing special to begin with. But our McPal, by its careful design, has the property to adapt the Paradigm model it belongs to. Process McPal is visualized in Figure 3.

Fig. 3. Process McPal.

In state obs, McPal is observing the model as a whole and possibly computing or perhaps hearing from elsewhere how to change the model. As soon as McPal arrives in state startMigr, it knows the new consistency rules according to which the executing model is going to migrate uninterruptedly towards a new model. This migration is coordinated by McPal outside its state obs. To

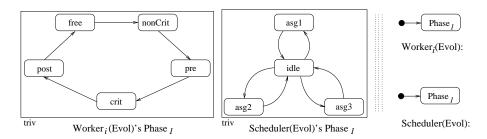

Fig. 4. Evolutionary phases and evolutionary processes to begin with

support the migration, every other detailed process has an additional partition called Evol. It contains the subprocesses reflecting the evolutionary phases so-far of that particular detailed process. As long as McPal is in state obs for the first time, each such partition consists of exactly one subprocess, here called Phase₁, always being the full, unconstrained process itself, typically with the trivial trap connecting from Phase₁ towards an as yet unknown subprocess reflecting an intermediate migration phase. Figure 4 presents the Evol partitions for Worker_i as well as for Scheduler together with the degenerate global processes at the level of these partitions. All other partitions are unchanged. The consistency rules for the extended model are the original rules together with only one new rule for McPal, viz. consistency rule (3) below, for the moment.

$$McPal: obs \rightarrow startMigr * [CR := CR \cup CR_{mig} \cup CR_{next}]$$
 (3)

This one rule is a change clause: as the set of consistency rules we start with, is going to change during the migration, the set of consistency rules is bound to a local variable of McPal, here denoted as CR. Change clause (3) should be taken parametrically, i.e., at the very moment process McPal decides to take the transition from its state obs to state startMigr, the collection of consistency rules gets updated via the assignment in the change clause with the whole of consistency rules in CR, CR_{mig} and CR_{next} at that moment. So the effect of the change clause (3) fully depends on the actual values of its two parameters CR_{mig} and CR_{next} . As we shall see later, McPal determines the pace of evolution.

With respect to the new detailed process McPal it is important to note, only the first transition of McPal, from state obs to startMigr is supported

by a consistency rule. This means, in the first phase of the evolution the other transitions cannot occur. But, as a result of this, one possible transition in McPal, the set CR of consistency rules is extended with two more sets: one, CR_{mig} , for the intermediate phase proper and the other, CR_{next} , for the next evolutionary phase. In particular, once CR_{mig} is known, there are consistency rules for the other McPal transitions too, readily made, JIT-modeled (just in time), either by computational effort of McPal while in state obs, or by modeling effort from outside McPal and given as input to McPal while in state obs.

For this paper we shall keep process McPal unchanged. This means, we choose one particular form of sufficiently useful standard behaviour of McPal for actually coordinating the migration steps of other processes involved. By its first transition $\mathtt{obs} \to \mathtt{startMigr}$, McPal extends via change clause (3) the rules, such that other processes' Phase₁ constraint is going to be relaxed, if necessary. For the examples we want to discuss here, three more migration steps will do: a transition $\mathtt{startMigr} \to \mathtt{contMigr}$ for continuing the migration, only if necessary, by adjusting the migration already begun; a transition $\mathtt{contMigr} \to \mathtt{endMigr}$ for restraining the other processes' constraints to the Phase₂ behaviours aimed at, thus closing their migration; the last one, transition $\mathtt{endMigr} \to \mathtt{obs}$, for restraining the migrational freedom for McPal too, thus preventing McPal in some unknown future to repeat an old migration when a new one is in place. In the next two sections we present some concrete self-adapting Paradigm models and provide detail for McPal's remaining three transitions.

The combined starting states of the Paradigm model are grouped according to the five detailed processes:

```
\begin{aligned} & (\mathsf{Worker}_i, \mathsf{Worker}_i(\mathsf{CSM}), \mathsf{Worker}_i(\mathsf{Evol})) : (\mathsf{free}, \mathsf{Free}, \mathsf{Phase}_1), \\ & (\mathsf{Scheduler}, \mathsf{Scheduler}(\mathsf{Evol})) : (\mathsf{idle}, \mathsf{Phase}_1), \\ & & \mathsf{McPal} : \mathsf{obs}. \end{aligned}
```

4 Reducing the Extent of Exclusive Behaviour

The example variants presented in this section exhibit a restricted form of self-adaptation through step-wise modification of non-evolutionary global behaviours only, i.e. exclusively at the level of the three $\mathsf{Worker}_i(\mathsf{CSM})$ partitions. For the moment, the detailed worker and scheduler processes are not going to change at all, so their Phase_1 subprocess constraints remain unchanged during the evolution as discussed here. The non-evolutionary global processes $\mathsf{Worker}_i(\mathsf{CSM})$ do change, however.

To become more concrete, suppose we want to modify the original mutual exclusion management in two ways: by substantially restricting the exclusive behaviour as well as by making the return to non-critical working most asynchronous. These two improvements are realized by the new subprocesses OutCS and InCS, drawn in Figure 5, with their traps entering and left. Trap entering has been chosen as 'near' to state crit and as 'small' as possible. Trap

left has been chosen as 'large' as possible –the larger the more asynchronous—and starting 'immediately after' state crit.

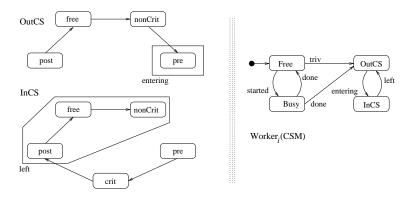

Fig. 5. Extensions of partition CSM and of global process $Worker_i(CSM)$

nal consistency rules in CR, the consistency rules CR_{mig} that guide the migration, and the consistency rules CR_{next} for the next evolutionary phase. The original consistency rules are bound to McPal's local variable CR, that is to say, CR has the rules mentioned in Section 3 as initial value. The consistency rules CR_{mig} for the migration are the following.

```
\begin{split} & \text{McPal:startMigr} \rightarrow \text{contMigr} \\ & \text{McPal:contMigr} \rightarrow \text{endMigr} * \text{Worker}_1(\text{CSM}) \text{: OutCS} \xrightarrow{triv} \text{OutCS} \\ & \text{McPal:endMigr} \rightarrow \text{obs} * [\text{CR} := \text{CR}_{next}] \\ & \text{Scheduler:asg}_i \rightarrow \text{idle} * \text{Worker}_i(\text{CSM}) \text{: Busy} \xrightarrow{done} \text{OutCS}, \\ & \text{Worker}_{i-1}(\text{CSM}) \text{: Free} \xrightarrow{triv} \text{OutCS}, \text{Worker}_{i+1}(\text{CSM}) \text{Free} \xrightarrow{triv} \text{OutCS} \end{split}
```

Here i-1 and i+1 denote the usual predecessor and successor values of i in the cyclic order of 1, 2, 3.

The first rule for McPal above states that, in this migration, there is no coordination task for McPal in the first step. The second rule for McPal expresses that the migration has been completed, when the first worker runs restricted to the OutCS subprocess at the level of its CSM partition. Once in state endMigr, McPal cleans up the old and intermediate consistency rules by binding CR to CR_{next} and comes back in state obs again. Here the actual migration is in the new rule for Scheduler. When returning from any of the states asg_1 , asg_2 , asg_3 ,

all workers, including the Worker₁ that is checked by McPal, are transfered to subprocess OutCS of the next evolution phase. Note, the actual migration is not really enforced: Scheduler might carry on with the old coordination forever. As soon as the new consistency rule has been applied, however, migration has taken place irreversibly.

The consistency rules CR_{next} for the next evolutionary phase, the new solution we are actually aiming at, are

```
\begin{split} & \operatorname{Worker}_i \colon \mathsf{free} \to \mathsf{nonCrit} & \operatorname{Worker}_i \colon \mathsf{crit} \to \mathsf{post} \\ & \operatorname{Worker}_i \colon \mathsf{nonCrit} \to \mathsf{pre} & \operatorname{Worker}_i \colon \mathsf{post} \to \mathsf{free} \\ & \operatorname{Worker}_i \colon \mathsf{pre} \to \mathsf{crit} \\ & \operatorname{Scheduler} \colon \mathsf{idle} \to \mathsf{asg}_i \ * \ \operatorname{Worker}_i(\mathsf{CSM}) \colon \mathsf{OutCS} \overset{entering}{\to} \mathsf{InCS} \\ & \operatorname{Scheduler} \colon \mathsf{asg}_i \to \mathsf{idle} \ * \ \operatorname{Worker}_i(\mathsf{CSM}) \colon \mathsf{InCS} \overset{left}{\to} \mathsf{OutCS} \\ & \operatorname{McPal} \colon \mathsf{obs} \to \mathsf{startMigr} \ * \ [ \mathsf{CR} \ \colon = \ \mathsf{CR} \cup \mathsf{CR}_{mig} \cup \mathsf{CR}_{next} ] \end{split}
```

In the new evolution phase, the same scheduler continues to coordinate the same workers with more parallelism between the workers, now the extent of the exclusive, critical working interval has been reduced and trap left allows for a most asynchronous continuation of a worker after having finished his critical activity. The change clause for McPal for the transition from obs to startMigr caters for later evolution, at McPal's leisure.

Figure 6 might be viewed as a movie of global process $Worker_i(CSM)$ represented through three subsequent takes reflecting subsequent migration. The first

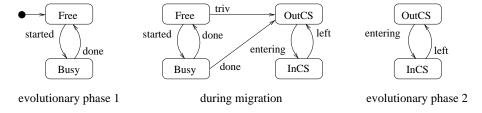

Fig. 6. Migration of process $Worker_i(CSM)$, first variant

take of the movie lasts until McPal leaves state obs. The second take lasts while McPal is in its three states startMigr, contMigr and endMigr. Upon arrival in state endMigr it is guaranteed that the worker process executes either subprocess OutCS or InCS. The third take starts when McPal returns in state obs.

An interesting variant, slightly different only, is McPal's first migration rule in the above set CR_{mig} replaced by

```
\texttt{McPal:startMigr} \rightarrow \texttt{contMigr} \ * \ \big[ \ \texttt{CR} \ := \ \texttt{CR} \backslash \texttt{CR}_{help} \ \big]
```

where CR_{help} has been computed or has been read from input in state obs, consisting of the 'migration avoiding' rules

$$\texttt{Scheduler:} \, \texttt{asg}_i \to \texttt{idle} \, \, * \, \, \texttt{Worker}_i(\texttt{CSM}) \text{:} \, \texttt{Busy} \overset{done}{\to} \texttt{Free}$$

The consequence thereof is, from McPal's arrival in state contMigr, the migration is more enforcing towards Phase₂, the actual evolutionary phase aimed at. The movie now consists of four takes, see Figure 7. The enforcing is an exam-

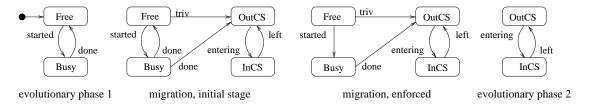

Fig. 7. Migration of process $Worker_i(CSM)$, second variant

ple of migration adjusting. Note, we have indeed specified the self-adaptation through new global behaviour at the level of $\mathtt{Worker}_i(\mathtt{CSM})$ only, leaving all detailed behaviours untouched.

5 Changing Scheduling Order

This section presents example variants of self-adaptation affecting a detailed process and involving non-trivial global behaviour at the level of partition Evol of that detailed process, really evolutionary behaviour in terms of subsequent phases.

To this aim, we reorganize the Paradigm model of Section 3 in a different way, namely by changing the non-deterministic selection policy of the scheduler into round robin selection. Figure 8 visualizes a combination of the original scheduler process and a new, envisaged one. The four upper states, of the seven states displayed, constitute the STD of the Scheduler process as in Figure 1. The six lower states, asg₁ to asg₃ and check₁ to check₃, will comprise the state space of the evolved Scheduler process. So, here we have a different type of change: a detailed process is going to get new behaviour. Round robin checking of a worker's wish to enter its critical section, is done in the states $check_i$, whereas the meaning of states asg, is kept unchanged. The combined behaviours as presented in Figure 8 actually obscure what transitions could be taken during which evolutionary phase. At level of the partition Evol this becomes rather more clear from global process Scheduler (Evol). Figure 9 presents the partition Evol of the extended process Scheduler under migration, together with global process Scheduler(Evol). Without the traps and with idle added as starting state of the first evolutionary phase, it can be taken as a movie of process Scheduler's evolution represented through three subsequent takes. Consistency rules for the

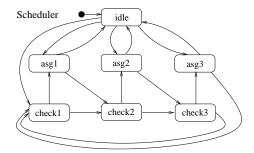

Fig. 8. Combined STD of two incarnations of Scheduler

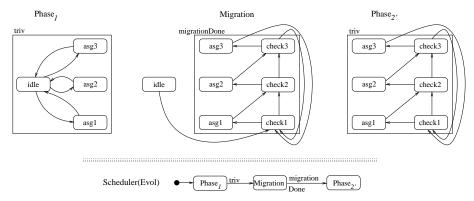

Fig. 9. Partition Evol of Scheduler, first variant

migration as well as for the new way of scheduling are grouped into the two sets \mathtt{CR}_{mig} and \mathtt{CR}_{next} , like before. Remember, we start with \mathtt{CR} as modeled in Section 3. As before, i+1 denotes the successor of i from the cyclic values 1,2,3.

In addition, we use the negative side rule $P(\pi)\colon S\xrightarrow{\theta}$ for the condition that within partition π of process P either S is not the current subprocess, or trap θ of subprocess S has not yet been entered. This condition is necessary for the corresponding manager transition to occur and it leaves the current subprocess at the level of partition π of P unchanged. The consistency rules for the migration are now the following.

```
\begin{array}{c} {\tt McPal:startMigr} \rightarrow {\tt contMigr} \ * \\ & {\tt Scheduler(Evol):Phase_1} \stackrel{triv}{\rightarrow} {\tt Migration} \\ {\tt McPal:contMigr} \rightarrow {\tt endMigr} \ * \\ & {\tt Scheduler(Evol):Migration} \stackrel{migrationDone}{\rightarrow} {\tt Phase_2} \\ {\tt McPal:endMigr} \rightarrow {\tt obs} \ * \ [ {\tt CR} := {\tt CR}_{next} \ ] \\ {\tt Scheduler:idle} \rightarrow {\tt check_1} \end{array}
```

Please note, from the above list, the first rule for McPal starts the evolutionary migration phase for Scheduler. The one rule of Scheduler expresses the actual migration step, by going from idle to $check_1$. The second rule of McPal stabilizes the migration: Scheduler is in evolutionary phase Phase₂ from the moment the rule is applied. McPal's last rule then discards rules no longer needed, by keeping those from CR_{next} only. It may happen, that the actual migration step to be taken by Scheduler does not occur, as Scheduler, while in asg_i , gets its phase Migration as the current subprocess constraint. In that case, Scheduler migrates right then implicitly, without taking an explicit step. As an aside, we have a non-trivial management relation: McPal manages the scheduler, while the scheduler manages the workers.

The consistency rules \mathtt{CR}_{next} for the envisioned evolutionary phase are the following

```
\begin{array}{lll} \operatorname{Worker}_i \colon \operatorname{free} \to \operatorname{nonCrit} & \operatorname{Worker}_i \colon \operatorname{crit} \to \operatorname{post} \\ \operatorname{Worker}_i \colon \operatorname{nonCrit} \to \operatorname{pre} & \operatorname{Worker}_i \colon \operatorname{post} \to \operatorname{free} \\ \operatorname{Worker}_i \colon \operatorname{pre} \to \operatorname{crit} \\ & \operatorname{Scheduler} \colon \operatorname{check}_i \to \operatorname{asg}_i \ * \ \operatorname{Worker}_i(\operatorname{CSM}) \colon \operatorname{Free} \overset{started} \to \operatorname{Busy} \\ & \operatorname{Scheduler} \colon \operatorname{asg}_i \to \operatorname{check}_{i+1} \ * \ \operatorname{Worker}_i(\operatorname{CSM}) \colon \operatorname{Busy} \overset{done} \to \operatorname{Free} \\ & \operatorname{Scheduler} \colon \operatorname{check}_i \to \operatorname{check}_{i+1} \ * \ \operatorname{Worker}_i(\operatorname{CSM}) \colon \operatorname{Free} \overset{started} \to \\ & \operatorname{McPal} \colon \operatorname{obs} \to \operatorname{startMigr} \ * \ [\operatorname{CR} \ := \operatorname{CR} \cup \operatorname{CR}_{miq} \cup \operatorname{CR}_{next}] \end{array}
```

Figure 10 gives an alternative for partition Evol of the Scheduler process: during migration it allows for some extra delay of introducing the round robin approach, by a kind of last-orders possibility for at most one worker according to the old-fashioned non-deterministic selection mechanism. (See the transition from state idle to the states \mathtt{asg}_i in subprocess Migration.) Note that by thus changing

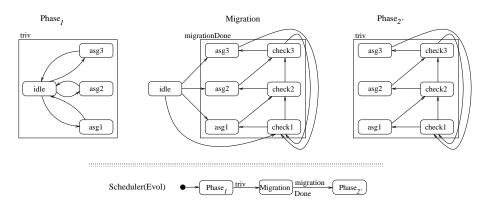

Fig. 10. Partition Evol of Scheduler, second variant

the definition of subprocess Migration, i.e. the concrete constraint, we do not

have to change our consistency rule formulations for achieving the evolution as depicted in Figure 10.

6 Conclusions, Related Work and Future Work

The scheduler and worker examples illustrate evolution on-the-fly as supported in Paradigm. The detailed transitions of the special component McPal mark the various migration steps from one evolutionary stage of the system to the next. Via consistency rules, new subprocesses of old or new behaviour can be introduced. Change clauses for McPal provide these consistency rules and dispose of coordination that is not desired any more. Although, the mechanism of subprocesses constrain the behaviour of components, the proposed evolution scheme itself does not require any component to stop, to be restarted later with new behaviour installed. In this sense, evolution is on-the-fly.

The evolution pattern as described allows for iterated evolution, as the McPal process is persistent in the model. A new migration can take place as soon as new consistency rules for intermediate and targeted behaviour and interaction are defined. With new semantics specified lazily, just-in-time, the self-adaptation is on-the-fly. In its present form, only one intermediate stage is foreseen in the evolution pattern, represented by the state contMigr of the detailed process of McPal. In the first evolution example variant, we have seen that this state was superfluous. The opposite, having more than one intermediate migration stage, is possible as well. Even stronger, the detailed behaviour of McPal can be specified just-in-time, determining the migration trajectory on-the-fly too. As such, our scheme provides unconstrained run-time selection of a migration trajectory. In general, any finite DAG with a unique starting state will do, as far as the structure of McPal is concerned.

Related work The contracts of Colman and Han [6] for the coordination of loosely coupled systems connect the organizational and functional views on an architecture, a distinction reminiscent to our managers and employees. The connection of Colman and Han, though, is by role instantiation, mapping the abstract to the concrete. Fundamental for Paradigm is the coupling of detailed state transitions with global subprocess transfer.

In the context of Component Based Software Engineering, adaptation is to be understood as component adaptation for interoperability purposes. Formal descriptional approaches are gaining impact in this field [2, 19, 16, 4], moving from IDLs based on finite state machines towards mobility-oriented process calculi and induced bisimulation equivalences. Although Paradigm is supported by a transition-based operational semantics [12], at present the behavioural theory to compare different evolutions or different stages within the same evolution, is not yet fully established. However, see [3, 13].

Oriol proposes to exploit asynchronous channels to drive unanticipated software evolution [17]. Leading principles are anonymity of entities, late binding and asynchronous communication in a setting of service-directed architectures. A variation geared towards tuple spaces has been reported in [18]. Because of the

atomicity of the services involved, the granularity is more coarse-grained than in the approach presented here, however.

There is a vast amount of literature on dynamic updating at the code level, for example on concrete dynamic software updating systems design (see e.g. [15, 20]). In the context of declarative programming, dynamic logic programming (see [1] amongst others) involves sequences of logic programs to express the evolution of knowledge over time. Controls have to be put in place to deal with inconsistencies among separate programs and to fine-tune asserts and retracts of Horn clauses. However, as with the work on imperative programming languages mentioned above, as yet no migration pattern or architectural support is provided to guide the evolution.

In addition, we like to mention [9, 10] as examples reporting on self-adaptive systems on an architectural level. In these papers there is the same tendency as noted above (service atomicity) of concentrating on forms of self-adaptation referred to as: reconfiguration, structured reorganization, data-driven readjustment, canned workflows being triggered, recomposition and the like. The survey [5] compares fourteen different approaches to self-adaptation, none of which appears to achieve so-called unconstrained run-time selection. Our McPal pattern however, allows for exactly this: the outcome of our JIT-modeling, occurring while being in state obs, fully determines such run-time freedom: nothing happening during migration or during later evolutionary phases has been foreseen from the beginning. The paper [7] is coming closest to our approach. It draws attention to the dynamic consistency problem, which should be solved by coordination; details about how to do this, are not given however, contrarily to our McPal component which, based on Paradigm, specifies such coordination in detail.

Future work Further research will be devoted to more elaborate migration schemes. A case study of the dining philosophers evolving from deadlock to starvation and beyond is under way. For the treatment of more intricate evolution patterns, dynamic creation and deletion of complete detailed processes is involved, which requires extension of Paradigm's formal semantics. Larger software architectures, for example in a setting of changes at the business level requiring software adaptation of lower-level support-systems, are likely to become multi-tier. Concise models will benefit from higher-order consistency rules and coordination patterns. Thesis work is devoted to tooling that supports the analysis of extensive examples as well as refactoring, transformation and refinement strategies of Paradigm models.

Acknowledgment We are indebted to our colleagues of the FaST-group, including Fahrad Arbab, Frank de Boer, Marcello Bonsangue, Jetty Kleijn, and Andries Stam for various stimulating discussions on the subject.
