Abstract
We describe efficient algorithms to search for cases in which binomial coefficients are equal or almost equal, give a conjecturally complete list of all cases where two binomial coefficients differ by 1, and give some identities for binomial coefficients that seem to be new.

1 Introduction
Let us call a quadruple \((n, k, m, l)\) with \(2 \leq k \leq \frac{1}{4}n\) and \(2 \leq l \leq \frac{1}{4}m\) a (binomial) collision when \(k < l\) and \(\binom{n}{k} = \binom{m}{l}\), and a near collision when \(\binom{m}{l} - \binom{n}{k} = d > 0\) with \(\binom{m}{l} \geq d^3\). The exponent 3 is somewhat arbitrary. Maybe 5 is a more natural exponent, see the end of this paper.

Collisions have been studied by many authors. Some references will be given below. In this note we report on computer searches for collisions and near collisions, and give seven infinite families of near collisions.

2 Collisions
We list the known collisions. There are the double collision
\[
\binom{78}{2} = \binom{15}{5} = \binom{14}{6} = 3003,
\]
six further sporadic examples given in the table below:

<table>
<thead>
<tr>
<th>(n)</th>
<th>(k)</th>
<th>(m)</th>
<th>(l)</th>
<th>(\binom{m}{l}) = (\binom{n}{k})</th>
</tr>
</thead>
<tbody>
<tr>
<td>16</td>
<td>2</td>
<td>10</td>
<td>3</td>
<td>120</td>
</tr>
<tr>
<td>21</td>
<td>2</td>
<td>10</td>
<td>4</td>
<td>210</td>
</tr>
<tr>
<td>56</td>

</table>

and a miraculous infinite family given by
\[
\binom{F_{2i+2}F_{2i+3}}{F_{2i}F_{2i+3}} = \binom{F_{2i+2}F_{2i+3} - 1}{F_{2i}F_{2i+3} + 1} \text{ for } i = 1, 2, \ldots,
\]
where $F_i$ is the $i$th Fibonacci number (defined by $F_0 = 0$, $F_1 = 1$, $F_{i+1} = F_i + F_{i-1}$ for $i \geq 1$). The infinite family is due to Lind [9], and was rediscovered by several others such as Singmaster [15] and Tovey [18]. Examples are

\[
\binom{15}{5} = \binom{14}{6}, \quad \binom{104}{39} = \binom{103}{40}, \quad \binom{714}{272} = \binom{713}{273}, \quad \binom{4895}{1869} = \binom{4894}{1870}.
\]

Twenty years ago one of us conjectured

**Conjecture 2.1** ([20]) There are no other collisions than those given above.

The current status is as follows.

**Theorem 2.2** There are no unknown collisions in the following cases:

- $(k, l) = (2, 3), (2, 4), (2, 5), (2, 6), (2, 8), (3, 4), (3, 6), (4, 6), (4, 8),$
- $(m, l) = (n - 1, k + 1), (n - 1, k + 2), (n - 2, k + 1),$
- $n \leq 10^6,$
- $\binom{n}{k} \leq 10^{60}.$

**Proof.** The first two parts can be found in the literature.

The case $(k, l) = (2, 3)$ was settled in [2]. The case $(k, l) = (2, 4)$ was settled in [12], and also in [19]. The case $(k, l) = (2, 5)$ was settled in [5]. The cases $(k, l) = (2, 6), (2, 8), (3, 6), (4, 6), (4, 8)$ were settled in [16]. The case $(k, l) = (3, 4)$ was settled in Mordell [11] (actually, he solved an equivalent equation and seems not to have noted the relation to binomial coefficients).

The case $(m, l) = (n - 1, k + 1)$ was settled in [18] (and yields the infinite family). The cases $(m, l) = (n - 1, k + 2), (n - 2, k + 1)$ were settled in [17].

The last two parts are the results of computer searches we report on in this paper. Some details are given below. \(\square\)

Earlier computer searches handled $n \leq 10^3$ and $\binom{n}{k} \leq 10^{30}$ ([20]). In the literature one also finds finiteness results ([7], [4]), and results on the number of times an integer may occur as binomial coefficient ([14], [1], [8]).

### 2.1 Settling $n \leq 10^6$

In order to find all collisions with $n \leq N$ for some fixed $N$, generate a list of all values $\binom{n}{k}$ with $2 \leq k \leq n/2$ and $n \leq N$. Sort it, and compare successive elements to find duplicates.

Now the list has length about $\frac{1}{4}N^2$, and probably does not fit into memory. One approach is to split the list into parts, e.g. into the sublists consisting of all binomial coefficients between $10^{e-1}$ and $10^e$, for all relevant $e$. We tried this in Mathematica and did $N = 34000$ in 23h30m on a 2.6 GHz Intel i7.

A different approach is to have a table and a priority queue, both of size $N$. Both contain the same elements. Initially both contain the numbers $\binom{n+2}{2}$ for $n < N$. The priority queue is kept sorted. At each step the top two elements are compared for equality. Afterwards the top element is discarded. When $\binom{n+k}{k}$ is discarded, the new value $\binom{n+k+1}{k+1}$ is added, unless $k \geq n$. The new value needed
is computed from the old one via \( \binom{n+k+1}{k+1} = \binom{n+k}{k} + \binom{n+k}{k+1} \). Note that the value \( \binom{n+k}{k+1} \) is present in the table at index \( n-1 \) at the moment it is needed.

Computation time for the algorithms as described is cubic in \( N \) if the precise value of the binomial coefficients is computed, since not only the length of the list grows, but also the size of the numbers. Bounded precision suffices to ensure that (almost) collisions are unlikely, and reduces the time needed to \( O(N^2 \log N) \). Almost collisions still occur (for example, \((10^{2091}) = 1.25683931954534 \cdot 10^{16800}, \binom{209094}{99614} = 1.25683931954529 \cdot 10^{16800}\)). We used interval arithmetic to distinguish almost equal numbers, and full exact multiple length arithmetic in the few cases where the interval arithmetic did not suffice. We tried this in C, with a custom data type (since the usual data types do not handle large exponents, or are too slow), and did \( N = 10^6 \) in 56h14m on an old 2 GHz PC.

### 2.2 Settling \( \binom{n}{k} \leq 10^{60} \)

In order to find all collisions with \( \binom{n}{k} \leq M \) we handle each relevant pair \( (k,l) \) separately. Let \( l_{\text{max}} \) be the largest \( l \) such that \( \binom{2l}{l} \leq M \). As we saw, the pairs \( (k,l) \) with \( k < l \leq 4 \) have been done already, so it suffices to handle \( 5 \leq l \leq l_{\text{max}} \), and for each \( l \) the values of \( k \) with \( 2 \leq k \leq l-1 \), with \( k \geq 3 \) if \( l = 5 \).

Given a pair \( (k,l) \), let \( m_{\text{max}} \) be the largest \( m \) with \( \binom{m}{k} \leq M \). Make a list of all \( m \) with \( 2l \leq m \leq m_{\text{max}} \), and discard the \( m \) for which \( \binom{m}{k} \) cannot be of the form \( \binom{a}{k} \). What is left are possible collisions, and in practice only actual collisions are left.

The discarding is done via a sieving process. The function \( f(n) = \binom{n}{k} \) is a polynomial of degree \( k \) in the variable \( n \), with rational coefficients. The denominators of the coefficients have only prime factors \( \leq k \). For any prime \( p > k \) the function \( f \) induces a polynomial map from \( 
\F_p \) to itself. Let \( A(k,p) \) be the size of the image. Experience shows that \( A(k,p) \approx (1 - e^{-1})p \) when \( k \) is odd, and \( A(k,p) \approx (1 - e^{-1/2})p \) when \( k \) is even. See below for more remarks on this function \( A(k,p) \). Since \( 1 - e^{-1} = 0.63... \) and \( 1 - e^{-1/2} = 0.39... \), a significant fraction of all residues mod \( p \) cannot be of the form \( \binom{a}{k} \). Now pick \( p > l > k \), and look at \( \binom{n}{k} \) for \( 0 \leq a \leq p - 1 \). Whenever \( \binom{a}{k} \) is not in the mod \( p \) image of \( f \), discard all \( \binom{a}{k} \) with \( m \equiv a \pmod{p} \) from the list.

Repeating this sieving action for all primes less than 500 (stopping earlier when the list has become empty) we found all collisions up to \( M = 10^{60} \). The largest prime needed was \( p = 401 \). This took about 375 CPU hours total on a few old 2 GHz machines. For large \( l \) the upper bound \( m_{\text{max}} \) is small, and sieving is very quick. (In fact for \( l \geq 10 \) we sieved up to \( 10^{100} \).) The main part of the work are the pairs \( (k,l) = (3,5), (4,5) \), where the list has length roughly \( M^{1/3} \).

**On \( A(k,p) \)**

There is a lot of literature on the size of the image of a polynomial on \( \F_p \). For \( k = 3 \) and \( k = 4 \) the value of \( A(k,p) \) was found by Daublesky v. Sterneck [6]. One has \( A(3,p) = (2p + 1)/3 \) when \( p \equiv 1 \pmod{6} \), and \( A(4,p) = (3p + 4 + \chi(-1) + 2\psi(5) - 2\psi(10))/8 \) for \( p > 5 \), where \( \chi \) is the quadratic character. Birch \& Swinnerton-Dyer [3] showed that ‘general’ polynomials of degree \( k \) on \( \F_p \) have an image of size \( a_k p + O(\sqrt{p}) \) where \( a_k = \sum_{\chi}(-1)^i - 1 \frac{4}{p} \). We conjecture in our situation that the value \( A_k = \lim_{p \to \infty} \frac{A(k,2)}{p} \) exists, and equals \( A_k = a_k \) for odd
$k$, and $A_k = \sum_{i=1}^{k/2} (-1)^{i-1} \frac{1}{2^{i-1}}$ for even $k$. This is true for $k \leq 5$. Note that for even $k$ there is the symmetry $f(x) = f(k+1-x)$ explaining the smaller image size.

3 Near collisions

3.1 Difference 1

We know about the following examples with $d = 1$:

<table>
<thead>
<tr>
<th>$n$</th>

</table>

The above table is complete for the cases $(k,l), (l,k) = (2,3), (2,4), (2,6), (3,4), (4,6)$ (as one sees by finding all integral points on the corresponding elliptic curves), and for $(\binom{n}{k}) \leq 10^{30}$. We conjecture the following

**Conjecture 3.1** There are no other near collisions with difference 1 than those given above.

and, more generally,

**Conjecture 3.2** Given a fixed difference $d$, the number of near collisions with difference $d$ is finite.

The latter conjecture can be backed by standard heuristic arguments. The infinite family of collisions seems like a miracle.

The cases mentioned above correspond to (double covers of) elliptic curves in cubic Weierstrass form or in quartic form, and can be solved completely using e.g. Sage [13] or Magma [10]. See [16], Table 1, for the transformations from the binomial equations to the elliptic equations.
3.2 Infinite families

When $d$ is not fixed, there are a few infinite families.

\[
\begin{align*}
\left(\frac{12x^2 - 12x + 3}{3}\right) + \left(\frac{x}{2}\right) &= \left(\frac{24x^3 - 36x^2 + 15x - 1}{2}\right) \\
\left(\frac{12x^2 - 12x + 5}{3}\right) + \left(\frac{x}{2}\right) &= \left(\frac{24x^3 - 36x^2 + 21x - 4}{2}\right) \\
\left(\frac{60x^2 - 60x + 15}{5}\right) + \left(\frac{x}{2}\right) &= \left(\frac{a}{2}\right)
\end{align*}
\]

where $a = 3600x^5 - 9000x^4 + 8700x^3 - 4050x^2 + 905x - 77$,

\[
\left(\frac{60x^2 - 60x + 19}{5}\right) + \left(\frac{x}{2}\right) = \left(\frac{a}{2}\right)
\]

where $a = 3600x^5 - 9000x^4 + 9300x^3 - 4950x^2 + 1355x - 152$,

\[
\left(\frac{240x^2 - 240x + 62}{5}\right) + \left(\frac{3x - 1}{2}\right) = \left(\frac{a}{2}\right)
\]

where $a = 115200x^5 - 288000x^4 + 288000x^3 - 144000x^2 + 35995x - 3597$,

\[
\left(\frac{11340x^2 + 11340x + 2835}{9}\right) + \left(\frac{y}{2}\right) = \left(\frac{a}{2}\right)
\]

where $y = 22680x^3 + 34020x^2 + 17001x + 2831$ and $a = 4134207084840000x^9 + 18603931881780000x^8 + 372013015300920000x^7 + 433862065736820000x^6 + 325024326359359000x^5 + 16249739546454750x^4 + 3411800836959550x^3 + 1158443736409575x^2 + 144626588131776x + 8023467184451$,

\[
\left(\frac{11340x^2 + 11340x + 2843}{9}\right) + \left(\frac{y}{2}\right) = \left(\frac{a}{2}\right)
\]

where $y = 22680x^3 + 34020x^2 + 17019x + 2840$ and $a = 4134207084840000x^9 + 18603931881780000x^8 + 372144259970280000x^7 + 4338621207938820000x^6 + 325913360873499000x^5 + 183475109089299750x^4 + 5440510606648950x^3 + 1167066670132675x^2 + 146062077851076x + 8126002273751$.

How does one find such identities? In order to get \(\binom{4}{1} + \binom{4}{2} = \binom{4}{3}\), where \(x\) is small, one needs \(\frac{1}{4}b(b - 1)(b - 2) = (a - x)(a + x - 1)\), a product of two nearly equal numbers. If \(b = 3e^2\), then \(\frac{1}{4}b(b - 1)(b - 2) = (e(b - 2))(e(b - 1))\) and we can take \(a - x = e(b - 2)\), \(a + x - 1 = e(b - 1)\) and find \(e = 2x - 1\), \(b = 3(2x - 1)^2\), the first family. The other families arise in a similar way.

Are there many such identities? Let us say that the quality of an identity \((n_i) + d(x) = (m_i)\) is the degree of \(x\) in \((n_i)\) and \((m_i)\) divided by that in \(d(x)\). Then our identities (1)-(7) have qualities 3, 3, 5, 5, 5, 3, 3. These are the only identities of quality at least 3 that we know of. Maybe there are no others. Maybe there is a number \(\alpha\), such that there are only finitely many identities of quality at least \(\alpha\).

It follows from the existence of the identities (1)-(7) that there are infinitely many near collisions, even with \(\binom{m}{1} \geq d^5\). Maybe there is a number \(\beta\), certainly \(\beta > 5\), such that there are only finitely many near collisions with \(\binom{m}{1} \geq d^\beta\).
