#### Abstract

SPL verification can be costly when all the software products of an SPL are verified independently. It is well known that parity games can be used to verify software products. We propose a generalization of parity games, named variability parity games (VPGs), that encode multiple parity games in a single game graph decorated with edge labels expressing variability between the parity games. We show that a VPG can be constructed from a modal $\mu$-calculus formula and an FTS that models the behaviour of the different software products of an SPL. Solving the resulting VPG decides for which products in the SPL the formula is satisfied. We introduce several algorithms to efficiently solve VPGs and exploit commonalities between the different parity games encoded. We perform experiments on SPL models to demonstrate that the VPG algorithms indeed outperform independently verifying every product in an SPL.

## 1. Introduction

Model verification techniques can be used to improve the quality of software. These techniques require the behaviour of the software to be modelled and these models can then be checked to verify that they behave conforming to some formally specified requirement. These verification techniques are well-studied, specifically techniques to verify a single software product.
Software product lines (SPLs) are systems that can be configured to result in different variants of the same system [12, 32]. SPLs describe families of software products where the products originate from the same system and often times have a lot of commonalities. The difference between the products in a family is called the variability of the family 40. A family of products can be verified by using traditional verification techniques to verify every single product independently. However, verifying models is expensive in term of computing power and the number of products in an SPL can grow large, therefore having to verify every single product independently is undesirable [11.
A common way of modelling the behaviour of software is by using labelled transition systems (LTSs) [22]. While LTSs can model behaviour well they cannot model variability. Efforts to also model variability include modal transition systems [14, 15, 38, I/O automata [26, 24] and featured transition systems (FTSs) [11, 8. Specifically the latter is well suited to model all the different behaviours of the software products as well as the variability of the entire system in a single model. FTSs use features to express variability; a feature is an option that can be turned on or off for the system. In the context of FTSs, a set of features is synonymous with a software product; an FTS describes the behaviour of a software product by enabling and disabling parts of the system based on the which features are enabled.

There are numerous temporal logics that can be used to formally express requirements. Examples include LTL, CTL, CTL* and modal $\mu$-calculus [31, 1, 22]. Of the different temporal logics, the modal $\mu$-calculus is the most expressive one; it subsumes the other temporal logics [28].

In this thesis we aim to verify the software products of an SPL in a collective manner that exploits commonalities between the different products. Given an FTS $M$, describing the set of products $P$, and a modal $\mu$-calculus formula, we explore methods to find the largest set of products $P_{s} \subseteq P$ such that all products in $P_{s}$ satisfy the formula. Specifically, we aim to verify SPLs more efficiently than verifying the products independently.

Parity games can be used to determine if an LTS behaves according to a modal $\mu$-calculus formula. Parity games are directed graphs that express a game played by two players 3. Every vertex in the graph is won by exactly one of the players and a parity game is globally solved when it is determined for every vertex who the winner is. A parity game can be constructed from an LTS and a modal $\mu$-calculus formula such that solving the parity game provides the information needed to determine if the LTS behaves according to the formula [3].
We introduce a generalization of parity games, called variability parity games (VPGs). A VPG expresses variability similar to how an FTS expresses variability. However, instead of using features a VPG expresses variability through configurations. Parity games have a winner for every vertex, VPGs have a winner for every vertex configuration combination. A VPG is globally solved when it is determined for every vertex configuration combination who the winner is. We introduce a way of constructing a VPG from an FTS and a modal $\mu$-calculus formula such that solving the VPG provides the information needed to determine which products, described by the FTS, behave according to the formula.

We introduce several algorithms to solve VPGs. We also introduce algorithms to partially solve

VPGs, in which case we only determine the winner of the vertex configuration combinations that are needed to determine which products, described by the FTS, behave according to the formula. This technique is called locally solving a VPG. We can also locally solve a parity game, where we only determine the winner of the vertex that is needed to determine if the LTS behaves according to the formula. Besides introducing local variants of the novel VPG algorithms we also introduce local variants of two well known parity game algorithms, namely the recursive algorithm [45, ,29] and the fixed-point iteration algorithm [43, 4].

Finally we implement the algorithms and compare their performances. We use two SPL models to create a number of VPGs. We compare the time it takes the algorithms to solve the VPGs with the time it takes to verify every product in the SPLs independently. For the independent verification approach we create parity games for all the products and requirements; these parity games are solved using existing parity game algorithms.

Through this experimental evaluation we show that we can indeed use a collective approach to more efficiently verify SPLs. The most efficient algorithm exploits commonalities between configuration by representing VPGs partially symbolic. This algorithm verifies the SPL properties 2 to 18 times quicker than an independent approach verifies them. Furthermore, we show that locally solving a VPG might improve the performance compared to globally solving a VPG; more so than locally solving a parity game improves the performance compared to globally solving a parity games.

Outline. First, we explore work related to model-checking SPLs in Chapter 2. Next, in Chapter 3, we introduce the following preliminary concepts: LTSs, $\mu$-calculus, parity games, model-checking using parity games, two parity game algorithms and symbolically representing sets. In Chapter 4 we formally introduce FTSs and the problem statement. We introduce VPGs in Chapter 5 and show that they can be used to model-check FTSs. We introduce VPG solving algorithms in Chapter 6 and in Chapter 7 we present local variants. Finally, we discuss the implementation and experimental results in Chapter 8 .

## 2. Related work

Prior work has been done to verify SPLs, we discuss four notable contributions.
In 11 a method is introduced to verify for which products in an FTS an LTL property holds. It does so by constructing a Büchi automaton representing the complement of the LTL property and checking if the synchronous product of the automaton and the transition system has an empty language 41. When applying this method to verify LTSs the reachability of the synchronous product is explored. For FTSs the paper introduces a reachability definition that determines for every product if a state is reachable. It is observed that a symbolic representation of the sets of products is advantageous when keeping track of the reachability. The paper uses the minepump example [25] to perform an experimental evaluation and find a substantial gain using verifying a family of products collectively as opposed to independently.

This work is expanded upon in [8]. The performance of such an approach is further elaborated upon and it is confirmed that a collective approach indeed outperforms an independent approach. Furthermore an extension of LTL is presented, namely featured LTL (fLTL). fLTL parametrizes LTL to be able to express properties in terms of features. Using this language one can distinguish between products when expressing temporal requirements.

In 10 symbolic model-checking is used to verify SPLs. fCTL is introduced as an extension of CTL that is able to reason about features. Verification of a CTL property can be done by expressing the CTL property as a tree, its parse tree, and doing a bottom-up traversal of it, deciding at every node what states satisfy the subformula. The paper proposes a way to symbolically represents FTSs, introduces a parse tree definition for the fCTL language and introduces an algorithm to do a bottom-up traversal of a fCTL parse tree, deciding at every node which state-product pairs satisfy it. These concepts are put in practice using the symbolic model checking toolset NuSMV [7] as a basis and extend the language to express variability. The paper uses the elevator example [30], modified to have 9 features, to show that symbolically model checking an SPL collectively using the methods proposed can significantly improve the performance compared to symbolically model checking all products independently.

Finally, in 36 an extension of the modal $\mu$-calculus, namely $\mu L_{f}$, is proposed that can reason about features. In [37] it is shown how properties expressed in $\mu L_{f}$ can be embedded in first order $\mu$-calculus and how the mCRL2 toolset [6] can be put to work to verify these properties. An algorithm is proposed that recursively partitions the products based on their features. After every partitioning the algorithm checks if the remaining set of products all satisfy the requirement or none of them satisfy the requirement. If either is true then that recursion is done, otherwise the algorithm continues. It is observed that the performance of this approach depends largely on deciding how to partition the sets of products. What would be a good heuristic/approach to splitting products is left unanswered in the paper.

## 3. Preliminaries

### 3.1 Fixed-point theory

A fixed-point of a function is an element in the domain of that function such that the function maps to itself for that element. Fixed-points are used in model verification as well as in some parity game algorithms.

Fixed-point theory goes hand in hand with lattice theory which we introduce first.

### 3.1.1 Lattices

We introduce definitions for ordering and lattices taken from [2].
Definition 3.1 ([2]). A partial order is a binary relation $x \leq y$ on set $S$ where for all $x, y, z \in S$ we have:

- $x \leq x$. (Reflexive)
- If $x \leq y$ and $y \leq x$, then $x=y$. (Antisymmetric)
- If $x \leq y$ and $y \leq z$, then $x \leq z . \quad$ (Transitive)

Definition 3.2 ([2]). A partially ordered set is a set $S$ and a partial order $\leq$ for that set, we denote a partially ordered set by $\langle S, \leq\rangle$.

Definition 3.3 ([2]). Given partially ordered set $\langle P, \leq\rangle$ and subset $X \subseteq P$. An upper bound to $X$ is an element $a \in P$ such that $x \leq$ a for every $x \in X$. A least upper bound to $X$ is an upper bound $a \in P$ such that every other upper bound is larger or equal to $a$.

The term least upper bound is synonymous with the term supremum, we write $\sup \{S\}$ to denote the supremum of set $S$.

Definition 3.4 ([2]). Given partially ordered set $\langle P, \leq\rangle$ and subset $X \subseteq P$. A lower bound to $X$ is an element $a \in P$ such that $a \leq x$ for every $x \in X$. A greatest lower bound to $X$ is a lower bound $a \in P$ such that every other lower bound is smaller or equal to $a$.

The term greatest lower bound is synonymous with the term infimum, we write $\inf \{S\}$ to denote the infimum of set $S$.

Definition 3.5 ([2]). A lattice is a partially ordered set where any two of its elements have a supremum and an infimum.

Definition 3.6 ( 2$]$ ). A complete lattice is a partially ordered set in which every subset has a supremum and an infimum.

Definition 3.7 ([2]). Given a lattice $\langle D, \leq\rangle$, function $f: D \rightarrow D$ is monotonic if and only if for all $x \in D$ and $y \in D$ it holds that if $x \leq y$ then $f(x) \leq f(y)$.

### 3.1.2 Fixed-points

Fixed-points are formally defined as follows:

Definition 3.8. Given function $f: D \rightarrow D$ the value $x \in D$ is a fixed-point for $f$ if and only if $f(x)=x$. Furthermore $x$ is the least fixed-point for $f$ if every other fixed-point for $f$ is greater or equal to $x$ and dually $x$ is the greatest fixed-point for $f$ if every other fixed-point $f$ is less or equal to $x$.

The Knaster-Tarski theorem states that least and greatest fixed-points exist for some domain and function given that a few conditions hold.

Theorem 3.1 (Knaster-Tarski[35]). Let

- $\langle A, \leq\rangle$ be a complete lattice,
- $f$ be a monotonic function on $A$ to $A$,
- $P$ be the set of all fixed-points of $f$.

Then the set $P$ is not empty and the system $\langle P, \leq\rangle$ is a complete lattice; in particular we have

$$
\sup P=\sup \{x \mid f(x) \geq x\} \in P
$$

and

$$
\inf P=\inf \{x \mid f(x) \leq x\} \in P
$$

### 3.2 Model verification

It is difficult to develop correct software, one way to improve reliability of software is through model verification; the behaviour of the software is specified in a model and formal verification techniques are used to show that the behaviour adheres to certain requirements. In this section we inspect how to model behaviour and how to specify requirements.

Behaviour can be modelled as a labelled transition system (LTS). An LTS consists of states in which the system can find itself and transitions between states. Transitions represent the possible state changes of the system. Transitions are labelled with actions that indicate what kind of change is happening. Formally we define an LTS as follows.

Definition 3.9 ([22]). A labelled transition system (LTS) is a tuple $M=\left(S\right.$, Act, trans, $\left.s_{0}\right)$, where:

- $S$ is a finite set of states,
- Act a finite set of actions,
- trans $\subseteq S \times A c t \times S$ is the transition relation with $\left(s, a, s^{\prime}\right) \in$ trans denoted by $s \xrightarrow{a} s^{\prime}$,
- $s_{0} \in S$ is the initial state.

An LTS is usually depicted as a graph where the vertices represent the states, the edges represent the transitions, edges are labelled with actions and an edge with no origin state indicates the initial state. Such a representation is depicted in the example below.

Example 3.1 ( 37 ). Consider the behaviour of a coffee machine that accepts a coin, after which it serves a standard coffee, this can be repeated infinitely often.

The behaviour can be modelled as an LTS that has two states: in the initial state it is ready to accept a coin and in the second state it is ready to serve a standard coffee. We introduce two actions: ins, which represents a coin being inserted, and std, which represents a standard coffee being served. We get the following LTS which is also depicted in Figure 3.1.

$$
\left(\left\{s_{1}, s_{2}\right\},\{s t d, i n s\},\left\{\left(s_{1}, i n s, s_{2}\right),\left(s_{2}, \text { std }, s_{1}\right)\right\}, s_{1}\right)
$$

Figure 3.1: Coffee machine LTS

LTSs might be non-deterministic, meaning that from a state there might be multiple transitions that can be taken. Moreover multiple transitions with the same action can be taken. This is depicted in the example below.

Example 3.2. We extend the coffee machine example such that at some point the coffee machine can be empty and needs to be filled before the system is ready to receive a coin again. This LTS is depicted in Figure 3.2. When the std transition is taken from state $s_{2}$ it is non-determined in which states the system ends up.

Figure 3.2: Coffee machine with non-deterministic behaviour

A system can be verified by checking if its behaviour adheres to certain requirements. The behaviour can be modelled in an LTS. Requirements can be expressed in a temporal logic; with a temporal logic we can express certain propositions with a time constraint such as always, never or eventually. For example (relating to the coffee machine example) we can express the following constraint: "After a coin is inserted the machine always serves a standard coffee immediately afterwards". The most expressive temporal logic is the modal $\mu$-calculus. A modal $\mu$-calculus formula is expressed over a set of actions and a set of variables.

We define the syntax of the modal $\mu$-calculus below. Note that the syntax is in positive normal form, i.e. no negations.

Definition 3.10 ([22]). A modal $\mu$-calculus formula over the set of actions Act and a set of variables $\mathcal{X}$ is defined by

$$
\varphi=\top|\perp| X|\varphi \vee \varphi| \varphi \wedge \varphi|\langle a\rangle \varphi|[a] \varphi|\mu X . \varphi| \nu X . \varphi
$$

with $a \in$ Act and $X \in \mathcal{X}$ ．
The modal $\mu$－calculus contains boolean constants $\top$ and $\perp$ ，propositional operators $\vee$ and $\wedge$ ， modal operators $\rangle$ and［］and fixed－point operators $\mu$ and $\nu$ ．

A variable $X \in \mathcal{X}$ occurs free in formula $\phi$ if and only if $X$ occurs in $\phi$ such that $X$ is not a sub－formula of $\mu X . \phi^{\prime}$ or $\nu X . \phi^{\prime}$ in $\phi$ ．A formula is closed if and only if there are no variables that occurs free．

A formula can be interpreted in the context of an LTS，such an interpretation results in a set of states in which the formula holds．Given formula $\varphi$ we define the interpretation of $\varphi$ as $\llbracket \varphi \rrbracket^{\eta} \subseteq S$ where $\eta: \mathcal{X} \rightarrow 2^{S}$ maps a variable to a set of states．We can assign $S^{\prime} \subseteq S$ to variable $X$ in $\eta$ by writing $\eta\left[X:=S^{\prime}\right]$ ，i．e．$\left(\eta\left[X:=S^{\prime}\right]\right)(X)=S^{\prime}$ ．

Definition 3.11 （［22］）．For LTS（ $S$, Act，trans，$s_{0}$ ）we inductively define the interpretation of a modal $\mu$－calculus formula $\varphi$ ，notation $\llbracket \varphi \rrbracket^{\eta}$ ，where $\eta: \mathcal{X} \rightarrow 2^{S}$ is a variable valuation，as a set of states where $\varphi$ is valid，by：

$$
\begin{aligned}
& \text { 【丁】" } \\
& =S \\
& \llbracket \perp \rrbracket^{\eta} \\
& =\emptyset \\
& \llbracket \varphi_{1} \wedge \varphi_{2} \rrbracket^{\eta} \\
& =\llbracket \varphi_{1} \rrbracket^{\eta} \cap \llbracket \varphi_{2} \rrbracket^{\eta} \\
& \llbracket \varphi_{1} \vee \varphi_{2} \rrbracket^{\eta} \\
& =\llbracket \varphi_{1} \rrbracket^{\eta} \cup \llbracket \varphi_{2} \rrbracket^{\eta} \\
& \llbracket\langle a\rangle \varphi \rrbracket^{\eta} \\
& =\left\{s \in S \mid \exists_{s^{\prime} \in S} \xrightarrow{a} s^{\prime} \wedge s^{\prime} \in \llbracket \varphi \rrbracket^{\eta}\right\} \\
& \llbracket[a] \varphi \rrbracket^{n} \\
& \llbracket \mu X . \varphi \rrbracket^{\eta} \\
& =\bigcap\left\{f \subseteq S \mid f \supseteq \llbracket \varphi \rrbracket^{\eta[X:=f]}\right\} \\
& \llbracket \nu X . \varphi \rrbracket^{\eta} \\
& \left.=\bigcup\{f \subseteq S \mid f \subseteq \llbracket \varphi]^{\eta[X:=f]}\right\} \\
& \llbracket X \rrbracket^{\eta} \quad=\eta(X)
\end{aligned}
$$

Since there are no negations in the syntax we find that every modal $\mu$－calculus formula is mono－ tone，i．e．if we have for $U \subseteq S$ and $U^{\prime} \subseteq S$ that $U \subseteq U^{\prime}$ holds then $\llbracket \varphi \rrbracket^{\eta[X:=U]} \subseteq \llbracket \varphi \rrbracket^{\eta\left[X:=U^{\prime}\right]}$ holds for any variable $X \in \mathcal{X}$ ．Using the Knaster－Tarski theorem（Theorem 3．1）we find that the least and greatest fixed－points always exist．

Given closed formula $\varphi$ ，LTS $M=\left(S, \operatorname{Act}\right.$ ， $\left.\operatorname{trans}, s_{0}\right)$ and $s \in S$ we say that $M$ satisfies formula $\varphi$ in state $s$ ，and write $(M, s) \models \varphi$ ，if and only if $s \in \llbracket \varphi \rrbracket^{\eta}$ ．If and only if $M$ satisfies $\varphi$ in the initial state do we say that $M$ satisfies formula $\varphi$ and write $M \models \varphi$ ．
Example 3.3 （37］）．Consider the coffee machine example from Figure 3．1，which we call $C$ ， and formula $\varphi=\nu X . \mu Y([i n s] Y \wedge[s t d] X)$ which states that action std must occur infinitely often over all infinite runs．Obviously this holds for the coffee machine，therefore we have $C \models \varphi$ ．

## 3．3 Parity games

A parity game is a game played by two players：player 0 （also called player even）and player 1 （also called player odd）．We write $\alpha \in\{0,1\}$ to denote an arbitrary player and $\bar{\alpha}$ to denote $\alpha$＇s opponent，i．e．$\overline{0}=1$ and $\overline{1}=0$ ．A parity game is played on a playing field which is a directed graph where every vertex is owned by either player 0 or player 1．Furthermore every vertex has a natural number，called its priority，associated with it．

Definition 3.12 (3). A parity game is a tuple $\left(V, V_{0}, V_{1}, E, \Omega\right)$, where:

- $V$ is a finite set of vertices partitioned in sets $V_{0}$ and $V_{1}$, containing vertices owned by player 0 and player 1 respectively,
- $E \subseteq V \times V$ is the edge relation,
- $\Omega: V \rightarrow \mathbb{N}$ is the priority assignment function.

Parity games are usually represented as a graph where vertices owned by player 0 are shown as diamonds and vertices owned by player 1 are shown as boxes. Furthermore the priorities are depicted as numbers inside the vertices. Such a representation is shown in the example below.

Example 3.4. Figure 3.3 shows the parity game:

$$
\begin{gathered}
V_{0}=\left\{v_{1}, v_{4}, v_{5}\right\}, V_{1}=\left\{v_{2}, v_{3}\right\}, V=V_{0} \cup V_{1} \\
E=\left\{\left(v_{1}, v_{2}\right),\left(v_{2}, v_{1}\right),\left(v_{1}, v_{3}\right),\left(v_{2}, v_{4}\right),\left(v_{3}, v_{4}\right),\left(v_{3}, v_{5}\right),\left(v_{4}, v_{4}\right)\right\} \\
\Omega=\left\{v_{1} \mapsto 2, v_{2} \mapsto 3, v_{3} \mapsto 0, v_{4} \mapsto 0, v_{5} \mapsto 1\right\}
\end{gathered}
$$

Figure 3.3: Parity game example

A parity game can be played for a vertex $v \in V$, we start by placing a token on vertex $v$. The player that owns vertex $v$ can choose to move the token along an edge to a vertex $w \in V$ such that $(v, w) \in E$. Again the player that owns vertex $w$ can choose where to move the token next. This is repeated either infinitely often or until a player cannot make a move, i.e. the token is on a vertex with no outgoing edges. Playing in this manner gives a sequence of vertices, called a path, starting from vertex $v$. For path $\pi$ we write $\pi_{i}$ to denote $i^{\text {th }}$ vertex in path $\pi$. Every path is associated with a winner (either player 0 or 1 ). If a player $\alpha$ cannot move at some point we get a finite path and player $\bar{\alpha}$ wins the path. If we get an infinite path $\pi$ then the winner is determined by the parity of the highest priority that occurs infinitely often in the path. Formally we determine the highest priority occurring infinitely often by the following formula.

$$
\max \left\{p \mid \forall_{j} \exists_{i} j<i \wedge p=\Omega\left(\pi_{i}\right)\right\}
$$

If the highest priority occurring infinitely often is odd then player 1 wins the path, if it is even player 0 wins the path.

A path is valid if and only if for every $i>0$ such that $\pi_{i}$ exists we have $\left(\pi_{i-1}, \pi_{i}\right) \in E$.

Example 3.5. Again consider the example in Figure 3.3. If we play the game for vertex $v_{1}$ we start by placing a token on $v_{1}$. Consider the following exemplary paths where $\left(w_{1} \ldots w_{m}\right)^{\omega}$ indicates an infinite repetition of vertices $w_{1} \ldots w_{m}$.

- $\pi=v_{1} v_{3} v_{5}$ is won by player 1 since player 0 cannot move at $v_{5}$.
- $\pi=\left(v_{1} v_{2}\right)^{\omega}$ is won by player 1 since the highest priority occurring infinitely often is 3 .
- $\pi=v_{1} v_{3}\left(v_{4}\right)^{\omega}$ is won by player 0 since the highest priority occurring infinitely often is 0 .

The moves that the players make are determined by their strategies. A strategy $\sigma_{\alpha}$ determines for a vertex in $V_{\alpha}$ where the token goes next. We can define a strategy for player $\alpha$ as a partial function $\sigma_{\alpha}: V^{*} V_{\alpha} \rightarrow V$ that maps a series of vertices ending with a vertex owned by player $\alpha$ to the next vertex such that for any $\sigma_{\alpha}\left(w_{0} \ldots w_{m}\right)=w$ we have $\left(w_{m}, w\right) \in E$. A path $\pi$ conforms to strategy $\sigma_{\alpha}$ if for every $i>0$ such that $\pi_{i}$ exists and $\pi_{i-1} \in V_{\alpha}$ we have $\pi_{i}=\sigma_{\alpha}\left(\pi_{0} \pi_{1} \ldots \pi_{i-1}\right)$.

A strategy is winning for player $\alpha$ from vertex $v$ if and only if $\alpha$ is the winner of every valid path starting in $v$ that conforms to $\sigma_{\alpha}$. If such a strategy exists for player $\alpha$ from vertex $v$ we say that vertex $v$ is winning for player $\alpha$.

Example 3.6. In the parity game seen in Figure 3.3 vertex $v_{1}$ is winning for player 1. Player 1 has a strategy that plays every vertex sequence ending in $v_{2}$ to $v_{1}$ and plays every vertex sequence ending in $v_{3}$ to $v_{5}$. Regardless of the strategy for player 0 the path will either end up in $v_{5}$ or will pass $v_{2}$ infinitely often. In the former case player 1 wins the path because player 0 can not move at $v_{5}$. In the latter case the highest priority occurring infinitely often is 3.

Parity games are known to be positionally determined [3]. Meaning that every vertex in a parity game is winning for exactly one of the two players. Also every player has a positional strategy that is winning starting from each of his/her winning vertices. A positional strategy is a strategy that only takes the current vertex into account to determine the next vertex, it does not look at previously visited vertices. Therefore we can consider a strategy for player $\alpha$ as a function $\sigma_{\alpha}: V_{\alpha} \rightarrow V$. Finally, it is decidable for each of the vertices in a parity game who the winner is [3].

A parity game is solved if the vertices are partitioned in two sets, namely $W_{0}$ and $W_{1}$, such that every vertex in $W_{0}$ is winning for player 0 and every vertex in $W_{1}$ is winning for player 1 . We call these sets the winning sets of a parity game. Solving parity games is in complexity class $\mathrm{UP} \cap \mathrm{CO}-\mathrm{UP}$ and $\mathrm{NP} \cap$ co-NP [23]. No polynomial algorithms are known, however finding a polynomial algorithm does not prove $\mathrm{P}=\mathrm{NP}$.

Finally, parity games are considered total if and only if every vertex has at least one outgoing edge. Playing a total parity game always results in an infinite path. We can make a non-total parity game total by adding two sink vertices: $l_{0}$ and $l_{1}$. Each sink vertex has only one outgoing edge, namely to itself. Vertex $l_{0}$ has priority 1 and vertex $l_{1}$ has priority 0 . Clearly if the token ends up in $l_{\alpha}$ then player $\alpha$ looses the game because with only one outgoing edge we only get a single priority that occurs infinitely often, namely priority $\bar{\alpha}$. For every vertex $v \in V_{\alpha}$ that does not have an outgoing edge we create an edge from $v$ to $l_{\alpha}$. In the original game player $\alpha$ lost when the token was in vertex $v$ because he/she could not move any more. In the total game player $\alpha$ can only play to $l_{\alpha}$ from $v$ where he/she still looses. So using this method vertices in the total game have the same winner as they had in the original game (except for $l_{0}$ and $l_{1}$ which did not exist in the original game). In general we try to only work with total games because
no distinction is required between finite paths and infinite paths when reasoning about them, however we will encounter some scenario's where non-total games are still considered.

### 3.3.1 Relation between parity games and model checking

Verifying LTSs against a modal $\mu$-calculus formula can be done by solving a parity game. This is done by translating an LTS in combination with a formula to a parity game, the solution of the parity game provides the information needed to conclude if the model satisfies the formula. This relation is depicted in Figure 3.4 .

Figure 3.4: LTS verification using parity games

We consider a method of creating parity games from an LTS and a modal $\mu$-calculus formula such that there is a special vertex $w$ in the parity game that indicates if the LTS satisfies the formula; if and only if $w$ is won by player 0 is the formula satisfied.

First we introduce the notion of unfolding. A fixed-point formula $\mu X . \varphi$ can be unfolded, resulting in formula $\varphi$ where every occurrence of $X$ is replaced by $\mu X . \varphi$, denoted by $\varphi[X:=\mu X . \varphi]$. Interpreting a fixed-point formula results in the same set as interpreting its unfolding as shown in $\left\lfloor 3\right.$; i.e. $\llbracket \mu X . \varphi \rrbracket^{\eta}=\llbracket \varphi\left[X:=\mu X . \varphi \rrbracket \rrbracket^{\eta}\right.$. The same holds for the fixed-point operator $\nu$.

Next we define the Fischer-Ladner closure for a closed $\mu$-calculus formula [34, 16]. The FischerLadner closure of $\varphi$ is the set $F L(\varphi)$ of closed formulas containing at least $\varphi$. Furthermore for every formula $\psi$ in $F L(\varphi)$ it holds that for every direct subformula $\psi^{\prime}$ of $\psi$ there is a formula in $F L(\varphi)$ that is equivalent to $\psi^{\prime}$.

Definition 3.13. The Fischer-Ladner closure of closed $\mu$-calculus formula $\varphi$ is the smallest set $F L(\varphi)$ satisfying the following constraints:

- $\varphi \in F L(\varphi)$,
- if $\varphi_{1} \vee \varphi_{2} \in F L(\varphi)$ then $\varphi_{1}, \varphi_{2} \in F L(\varphi)$,
- if $\varphi_{1} \wedge \varphi_{2} \in F L(\varphi)$ then $\varphi_{1}, \varphi_{2} \in F L(\varphi)$,
- if $\langle a\rangle \varphi^{\prime} \in F L(\varphi)$ then $\varphi^{\prime} \in F L(\varphi)$,
- if $[a] \varphi^{\prime} \in F L(\varphi)$ then $\varphi^{\prime} \in F L(\varphi)$,
- if $\mu X . \varphi^{\prime} \in F L(\varphi)$ then $\varphi^{\prime}\left[X:=\mu X . \varphi^{\prime}\right] \in F L(\varphi)$ and
- if $\nu X . \varphi^{\prime} \in F L(\varphi)$ then $\varphi^{\prime}\left[X:=\nu X . \varphi^{\prime}\right] \in F L(\varphi)$.

We also define the alternation depth of a formula.
Definition 3.14 (3). The dependency order on bound variables of $\varphi$ is the smallest partial order such that $X \leq_{\varphi} Y$ if $X$ occurs free in $\sigma Y . \psi$. The alternation depth of a $\mu$-variable $X$ in formula $\varphi$ is the maximal length of a chain $X_{1} \leq_{\varphi} \cdots \leq_{\varphi} X_{n}$ where $X=X_{1}$, variables $X_{1}, X_{3}, \ldots$ are $\mu$-variables and variables $X_{2}, X_{4}, \ldots$ are $\nu$-variables. The alternation depth of a $\nu$-variable is defined similarly. The alternation depth of formula $\varphi$, denoted adepth $(\varphi)$, is the maximum of the alternation depths of the variables bound in $\varphi$, or zero if there are no fixed-points.
Example 3.7. Consider the formula $\varphi=\nu X . \mu Y$. $([i n s] Y \wedge[s t d] X)$ which states that for an LTS with Act $=\{$ ins, std $\}$ the action std must occur infinitely often over all infinite runs. Since $X$ occurs free in $\mu Y .([i n s] Y \wedge[s t d] X)$ we have $\operatorname{adepth}(Y)=1$ and $\operatorname{adepth}(X)=2$.

As shown in [3], it holds that formula $\mu X . \psi$ has the same alternation depth as its unfolding $\psi[X:=\mu X \cdot \psi]$. Similarly for the greatest fixed-point.

Next we define the transformation from an LTS and a formula to a parity game.
 $\varphi$ to a parity game $\left(V, V_{0}, V_{1}, E, \Omega\right)$.
Vertices in the parity game are represented as pairs of states and sub-formulas. A vertex is created for every state with every formula in the Fischer-Ladner closure of $\varphi$. We define the set of vertices:

$$
V=S \times F L(\varphi)
$$

Vertices have the following owners, successors and priorities:

| Vertex | Owner | Successor $(s)$ | Priority |
| :--- | :--- | :--- | :--- |
| $(s, \perp)$ | 0 |  | 0 |
| $(s, \top)$ | 1 |  | 0 |
| $\left(s, \psi_{1} \vee \psi_{2}\right)$ | 0 | $\left(s, \psi_{1}\right)$ and $\left(s, \psi_{2}\right)$ | 0 |
| $\left(s, \psi_{1} \wedge \psi_{2}\right)$ | 1 | $\left(s, \psi_{1}\right)$ and $\left(s, \psi_{2}\right)$ | 0 |
| $(s,\langle a\rangle \psi)$ | 0 | $\left(s^{\prime}, \psi\right)$ for every $s \xrightarrow{a} s^{\prime}$ | 0 |
| $(s,[a] \psi)$ | 1 | $\left(s^{\prime}, \psi\right)$ for every $s \rightarrow s^{\prime}$ | 0 |
| $(s, \mu X . \psi)$ | 1 | $(s, \psi[X:=\mu X . \psi])$ | $2\lfloor\operatorname{adepth}(X) / 2\rfloor+1$ |
| $(s, \nu X . \psi)$ | 1 | $(s, \psi[X:=\nu X . \psi])$ | $2\lfloor\operatorname{adepth}(X) / 2\rfloor$ |

Since the Fischer-Ladner formulas are closed we never get a vertex ( $s, X$ ).
Example 3.8. Consider LTS $M$ in Figure 3.5 and formula $\varphi=\mu X .([a] X \vee\langle b\rangle \top)$ expressing that on any path reached by a's we can eventually do a baction.
The resulting parity game is depicted in Figure 3.6. Let $V$ denote the set of vertices of this parity game. There are two vertices with more than one outgoing edge. From vertex $\left(s_{1},[a](\mu X . \phi) \vee\right.$

Figure 3.5: LTS $M$
$\langle b\rangle \top)$ player 0 does not want to play to $\left(s_{1},\langle b\rangle \top\right)$ because he/she will not be able to make another move and will lose the path. From vertex $\left(s_{2},[a](\mu X . \phi) \vee\langle b\rangle \top\right)$ player 0 can play to $\left(s_{2},\langle b\rangle \top\right)$ to bring the play in $\left(s_{2}, \top\right)$ to win the path. We get the following winning sets:

$$
\begin{aligned}
& W_{1}=\left\{\left(s_{1},\langle b\rangle \top\right)\right\} \\
& W_{0}=V \backslash W_{1}
\end{aligned}
$$

With the strategies $\sigma_{0}$ for player 0 and $\sigma_{1}$ for player 1 being (vertices with one outgoing edge are omitted):

$$
\begin{aligned}
\sigma_{0}= & \left\{\left(s_{1},[a](\mu X . \phi) \vee\langle b\rangle \top\right) \mapsto\left(s_{1},[a](\mu X . \phi)\right),\right. \\
& \left.\left(s_{2},[a](\mu X . \phi) \vee\langle b\rangle \top\right) \mapsto\left(s_{2},\langle b\rangle \top\right)\right\} \\
\sigma_{1}= & \}
\end{aligned}
$$

Note that the choice where to go from $\left(s_{2},[a](\mu X . \phi) \vee\langle b\rangle \top\right)$ does not matter for the winning sets.

Figure 3.6: Parity game $\operatorname{LTS} 2 P G(M, \varphi)$ with $\phi=[a] X \vee\langle b\rangle \top$

Parity games created in this manner relate back to the model verification question; state $s$ in LTS $M$ satisfies $\varphi$ if and only if player 0 wins vertex $(s, \varphi)$. This is formally stated in the following theorem and proven in 3].

Theorem 3.2 ([3). Given $L T S M=\left(S\right.$, Act,trans, $\left.s_{0}\right)$, modal $\mu$-calculus formula $\varphi$ and state $s \in S$ it holds that $(M, s) \models \varphi$ if and only if $(s, \varphi) \in W_{0}$ for the game $\operatorname{LTS} 2 P G(M, \varphi)$.

### 3.3.2 Globally and locally solving parity games

Parity games can be solved globally or locally; globally solving a parity game means that for every vertex in the game it is determined who the winner is. Locally solving a parity game means that for a specific vertex in the game it is determined who the winner is. For some applications of parity games, including model checking, there is a specific vertex that needs to be solved to solve the original problem. Locally solving the parity game is sufficient in such cases to solve the original problem.

Most parity game algorithms (including the two considered next) are concerned with globally solving. When talking about solving a parity game we talk about globally solving it unless stated otherwise.

### 3.3.3 Parity game algorithms

Various algorithms for solving parity games are known, we introduce two of them. First Zielonka's recursive algorithm which is well studied and generally considered to be one of the best performing parity game algorithms in practice [39, 18]. We also inspect the fixed-point iteration algorithm which tends to perform well for model-checking problems with a low number of distinct priorities [33.

## Zielonka's recursive algorithm

First we consider Zielonka's recursive algorithm [45, 29], which solves total parity games. Pseudo code is presented in Algorithm 1 . Zielonka's recursive algorithm has a worst-case time complexity of $O\left(e * n^{d}\right)$ where $e$ is the number of edges, $n$ the number of vertices and $d$ the number of distinct priorities [17].

```
Algorithm 1 RecursivePG(parity game \(G=\left(V, V_{0}, V_{1}, E, \Omega\right)\) )
    if \(V=\emptyset\) then
        return \((\emptyset, \emptyset)\)
    end if
    \(h \leftarrow \max \{\Omega(v) \mid v \in V\}\)
    \(\alpha \leftarrow 0\) if \(h\) is even and 1 otherwise
    \(U \leftarrow\{v \in V \mid \Omega(v)=h\}\)
    \(A \leftarrow \alpha-\operatorname{Attr}(G, U)\)
    \(\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow\) RecursivePG \((G \backslash A)\)
    if \(W_{\bar{\alpha}}^{\prime}=\emptyset\) then
        \(W_{\alpha} \leftarrow A \cup W_{\alpha}^{\prime}\)
        \(W_{\bar{\alpha}} \leftarrow \emptyset\)
    else
        \(B \leftarrow \bar{\alpha}-\operatorname{Attr}\left(G, W_{\bar{\alpha}}^{\prime}\right)\)
        \(\left(W_{0}^{\prime \prime}, W_{1}^{\prime \prime}\right) \leftarrow\) RECURSIVEPG \((G \backslash B)\)
        \(W_{\alpha} \leftarrow W_{\alpha}^{\prime \prime}\)
        \(W_{\bar{\alpha}} \leftarrow W_{\bar{\alpha}}^{\prime \prime} \cup B\)
    end if
    return \(\left(W_{0}, W_{1}\right)\)
```

The algorithm solves $G$ by taking the set of vertices with the highest priority and choosing $\alpha$ such that $\alpha$ has the same parity as the highest priority. Next the algorithm finds set $A$ such that player $\alpha$ can force the play to one of these high priority vertices. Next this set of vertices is removed from $G$ and the resulting subgame $G^{\prime}$ is solved recursively.

If $G^{\prime}$ is entirely won by player $\alpha$ then we distinguish three cases for any path played in $G$. Either the path eventually stays in $G^{\prime}, A$ is infinitely often visited or the path eventually stays in $A$. In the first case player $\alpha$ wins because game $G^{\prime}$ was entirely won by player $\alpha$. In the second
and third case player $\alpha$ can play to the highest priority from $A$. The highest priority, which has parity $\alpha$, is visited infinitely often and player $\alpha$ wins.

If $G^{\prime}$ is not entirely won by player $\alpha$ we consider winning sets ( $W_{0}^{\prime}, W_{1}^{\prime}$ ) of subgame $G^{\prime}$. Vertices in set $W_{\bar{\alpha}}^{\prime}$ are won by player $\bar{\alpha}$ in $G^{\prime}$ but are also won by player $\bar{\alpha}$ in $G$. The algorithm tries to find all the vertices in $G$ such that player $\bar{\alpha}$ can force the play to a vertex in $W_{\bar{\alpha}}^{\prime}$ and therefore winning the game. We now have a set of vertices that are definitely won by player $\bar{\alpha}$ in game $G$. In the remainder of the game player $\alpha$ can keep the play from $W_{\bar{\alpha}}^{\prime}$ so the algorithm solves the remainder of the game recursively to find the complete winning sets for game $G$.

A complete explanation of the algorithm can be found in 45, we do introduce definitions for the attractor set and for subgames.

An attractor set is a set of vertices $A \subseteq V$ calculated for player $\alpha$ given set $U \subseteq V$ where player $\alpha$ has a strategy to force the play starting in any vertex in $A \backslash U$ to a vertex in $U$. Such a set is calculated by adding vertices owned by player $\alpha$ that have an edge to the attractor set and adding vertices owned by player $\bar{\alpha}$ that only have edges to the attractor set.

Definition 3.16 (45]). Given parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ and a non-empty set $U \subseteq V$ we inductively define $\alpha-\operatorname{Attr}(G, U)$ such that

$$
U_{0}=U
$$

For $i \geq 0$ :

$$
\begin{aligned}
& U_{i+1}=U_{i} \cup\left\{v \in V_{\alpha} \mid \exists v^{\prime} \in V: v^{\prime} \in U_{i} \wedge\left(v, v^{\prime}\right) \in E\right\} \\
& \cup\left\{v \in V_{\bar{\alpha}} \mid \forall v^{\prime} \in V:\left(v, v^{\prime}\right) \in E \Longrightarrow v^{\prime} \in U_{i}\right\}
\end{aligned}
$$

Finally:

$$
\alpha-\operatorname{Attr}(G, U)=\bigcup_{i \geq 0} U_{i}
$$

Example 3.9. Figure 3.7 shows an example parity game in which an attractor set is calculated for player 0 . For set $U_{2}$ no more vertices can be attracted so we found the complete attractor set.

The algorithm also creates subgames, where a set of vertices is removed from a parity game to create a new parity game.

Definition 3.17 (45). Given a parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ and $U \subseteq V$ we define the subgame $G \backslash U$ to be the game $\left(V^{\prime}, V_{0}^{\prime}, V_{1}^{\prime}, E^{\prime}, \Omega\right)$ with:

- $V^{\prime}=V \backslash U$,
- $V_{0}^{\prime}=V_{0} \cap V^{\prime}$,
- $V_{1}^{\prime}=V_{1} \cap V^{\prime}$ and
- $E^{\prime}=E \cap\left(V^{\prime} \times V^{\prime}\right)$.

Note that a subgame is not necessarily total, however the recursive algorithm always creates subgames that are total [45].

(a) Set $U=U_{0}$ highlighted

(b) Set $U_{1}$ highlighted

(c) Set $U_{2}=0-\operatorname{Attr}(G, U)$ highlighted

Figure 3.7: Game $G$ showing the attractor calculation for $0-\operatorname{Attr}(G, U)$

## Fixed-point iteration algorithm

Parity games can be solved by solving an alternating fixed-point formula 43. Consider parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ with $d$ distinct priorities. We can apply priority compression to make sure every priority in $G$ maps to a value in $\{0, \ldots, d-1\}$ or $\{1, \ldots, d\}$ [19, 4]. We assume without loss of generality that the priorities map to $\{0, \ldots, d-1\}$ and that $d-1$ is even.

Consider the following formula

$$
S(G)=\nu Z_{d-1} \cdot \mu Z_{d-2} \ldots \ldots \nu Z_{0} \cdot F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right)
$$

with

$$
\begin{aligned}
F_{0}\left(G=\left(V, V_{0}, V_{1}, E, \Omega\right), Z_{d-1}, \ldots, Z_{0}\right) & =\left\{v \in V_{0} \mid \exists_{w \in V}(v, w) \in E \wedge w \in Z_{\Omega(w)}\right\} \\
& \cup\left\{v \in V_{1} \mid \forall_{w \in V}(v, w) \in E \Longrightarrow w \in Z_{\Omega(w)}\right\}
\end{aligned}
$$

where $Z_{i} \subseteq V$. The formula $\nu X . f(X)$ solves the greatest fixed-point of $X$ in $f$, similarly $\mu X . f(X)$ solves the least fixed-point of $X$ in $f$. As shown in 43] formula $S(G)$ calculates the set of vertices winning for player 0 in parity game $G$.

To understand the formula we consider sub-formula $\nu Z_{0} \cdot F_{0}\left(Z_{d-1}, \ldots, Z_{0}\right)$. This formula holds for vertices from which player 0 can either force the play into a node with priority $i>0$ for which $Z_{i}$ holds or the player can stay in vertices with priority 0 indefinitely. The formula $\mu Z_{0} \cdot F_{0}\left(Z_{d-1}, \ldots, Z_{0}\right)$ holds for vertices from which player 0 can force the play into a node with priority $i>0$, for which $Z_{i}$ holds, in finitely many steps. By alternating fixed-points the formula allows infinitely many consecutive stays in even vertices and finitely many consecutive stays in odd vertices. For an extensive treatment we refer to 43.

We further inspect formula $S$. Given game $G$, consider the following sub-formulas:

$$
\begin{gathered}
S^{d-1}\left(Z_{d-1}\right)=\mu Z_{d-2} \cdot S^{d-2}\left(Z_{d-2}\right) \\
S^{d-2}\left(Z_{d-2}\right)=\nu Z_{d-3} \cdot S^{d-3}\left(Z_{d-3}\right) \\
\cdots \\
S^{0}\left(Z_{0}\right)=F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right)
\end{gathered}
$$

The fixed-point variables are all elements of $2^{V}$, therefore we have for every sub-formula the following type:

$$
S^{i}\left(Z_{i}\right): 2^{V} \rightarrow 2^{V}
$$

Furthermore, since $V$ is finite, the partially ordered set $\left\langle 2^{V}, \subseteq\right\rangle$ is a complete lattice; for every subset $X \subseteq 2^{V}$ we have infimum $\bigcap_{x \in X} x$ and supremum $\bigcup_{x \in X} x$. Finally every sub-formula $S^{i}\left(Z_{i}\right)$ is monotonic, i.e. if $S^{i}\left(Z_{i}\right) \geq S^{i}\left(Z_{i}^{\prime}\right)$ then $Z_{i} \geq Z_{i}^{\prime}$.

Fixed-point formulas can be solved by fixed-point iteration. As shown in [13] we can calculate $\mu X . f(X)$, where $f$ is monotonic in $X$ and $X \in 2^{V}$, by iterating $X$ :

$$
\mu X . f(X)=\bigcup_{i \geq 0} X^{i}
$$

where $X^{i}=f\left(X^{i-1}\right)$ for $i>0$ and $X^{0} \subseteq \mu X . f(X)$. So picking the smallest value possible for $X_{0}$ will always correctly calculate $\mu X . f(X)$.
Similarly we can calculate fixed-point $\nu X . f(X)$ when $f$ is monotonic in $X$ by iterating $X$ :

$$
\nu X \cdot f(X)=\bigcap_{i \geq 0} X^{i}
$$

where $X^{i}=f\left(X^{i-1}\right)$ for $i>0$ and $X^{0} \supseteq \nu X . f(X)$. So picking the largest value possible for $X_{0}$ will always correctly calculate $\nu X . f(X)$.

Since every subformula is monotonic and maps from a value in $2^{V}$ to another value in $2^{V}$ we can apply fixed-point iteration to solve the subformulas, we choose initial values $\emptyset$ for least fixed-point variables and $V$ for greatest fixed-point variables.
An algorithm to perform the iteration is presented in 4] and shown in Algorithm 2. This algorithm has a worst-case time complexity of $O\left(e * n^{d}\right)$ where $e$ is the number of edges, $n$ the number of vertices and $d$ the number of distinct priorities.

```
Algorithm 2 Fixed-point iteration
    function \(\operatorname{FPIter}\left(G=\left(V, V_{0}, V_{1}, E, \Omega\right)\right)\)
        for \(i \leftarrow d-1, \ldots, 0\) do
            Init \((i)\)
        end for
        repeat
            \(Z_{0}^{\prime} \leftarrow Z_{0}\)
            \(Z_{0} \leftarrow \operatorname{Diamond}() \cup \operatorname{Box}()\)
            \(i \leftarrow 0\)
            while \(Z_{i}=Z_{i}^{\prime} \wedge i<d-1\) do
                \(i \leftarrow i+1\)
                \(Z_{i}^{\prime} \leftarrow Z_{i}\)
                \(Z_{i} \leftarrow Z_{i-1}\)
                \(\operatorname{Init}(i-1)\)
            end while
        until \(i=d-1 \wedge Z_{d-1}=Z_{d-1}^{\prime}\)
        return \(\left(Z_{d-1}, V \backslash Z_{d-1}\right)\)
    end function
```

## function $\operatorname{Init}(i)$

$Z_{i} \leftarrow \emptyset$ if $i$ is odd, $V$ otherwise
end function

## function DiAmond

return $\left\{v \in V_{0} \mid \exists_{w \in V}(v, w) \in E \wedge w \in\right.$ $\left.Z_{\Omega(w)}\right\}$
end function

```
function Box
    return \(\left\{v \in V_{1} \mid \forall_{w \in V}(v, w) \in E \Longrightarrow\right.\)
\(\left.w \in Z_{\Omega(w)}\right\}\)
end function
```

### 3.4 Symbolically representing sets

A set can straightforwardly be represented by a collection containing all the elements that are in the set. We call this an explicit representation of a set. We can also represent sets symbolically in which case the set of elements is represented by some sort of formula. A typical way to represent a set symbolically is through a boolean formula encoded in a binary decision diagram [44, 5].

Example 3.10. The set $S=\{2,4,6,7\}$ can be expressed by boolean formula:

$$
F\left(x_{2}, x_{1}, x_{0}\right)=\left(\neg x_{2} \wedge x_{1} \wedge \neg x_{0}\right) \vee\left(x_{2} \wedge\left(x_{1} \vee \neg x_{0}\right)\right)
$$

where $x_{0}, x_{1}$ and $x_{2}$ are boolean variables. The formula gives the following truth table:

| $\mathbf{x}_{\mathbf{2}} \mathbf{x}_{\mathbf{1}} \mathbf{x}_{\mathbf{0}}$ | $\mathbf{F}\left(\mathbf{x}_{\mathbf{2}}, \mathbf{x}_{\mathbf{1}}, \mathbf{x}_{\mathbf{0}}\right)$ |
| :---: | :---: |
| 000 | 0 |
| 001 | 0 |
| 010 | 1 |
| 011 | 0 |
| 100 | 1 |
| 101 | 0 |
| 110 | 1 |
| 111 | 1 |

The function $F$ defines set $S^{\prime}$ in the following way: $S^{\prime}=\left\{x_{2} x_{1} x_{0} \mid F\left(x_{2}, x_{1}, x_{0}\right)=1\right\}$. As we can see set $S^{\prime}$ contains the same numbers as $S$, represented in binary format.

We can perform set operations on sets represented as boolean functions by performing logical
operations on the functions. For example, given boolean formulas $f$ and $g$ representing sets $V$ and $W$ the formula $f \wedge g$ represents set $V \cap W$.

Given a set $S$ with arbitrary elements we can represent subsets $S^{\prime} \subseteq S$ as boolean formulas by assigning a number to every element in $S$ and creating a boolean formula that maps boolean variables to true if and only if they represent a number such that the element associated with this number in $S$ is also in $S^{\prime}$.

### 3.4.1 Binary decision diagrams

A boolean function can efficiently be represented as a binary decision diagram (BDD). For a comprehensive treatment of BDDs we refer to [44, 5].

BDDs represent boolean formulas as a directed graph where every vertex represents a boolean variable and has two outgoing edges labelled 0 and 1. Furthermore the graph contains special vertices 0 and 1 that have no outgoing edges. We decide if a boolean variable assignment satisfies the formula by starting in the initial vertex of the graph and following a path until we get to either vertex 0 or 1 . Since every vertex represents a boolean formula, we can create a path from the initial vertex by choosing edge 0 at a vertex if the boolean variable represented by that vertex is false in the variable assignment and choosing edge 1 if it is true. Eventually we end up in either vertex 0 or 1 . In the former case the boolean variable assignment does not satisfy the formula, in the latter it does.

Example 3.11. Consider the boolean formula in Example 3.10. This formula can be represented as the BDD shown in Figure 3.8. The vertices representing boolean variables are shown as circles and the boolean variables they represent are indicated inside them. The special vertices are represented as squares and the initial vertex is represented by an edge that has no origin vertex.

Figure 3.8: BDD highlighting boolean variable assignment $x_{2} x_{1} x_{0}=011$ in blue and $x_{2} x_{1}=11$ in red

The path created from variable assignment $x_{2} x_{1} x_{0}=011$ is highlighted in blue in the diagram
and shows that this assignment is indeed not satisfied by the boolean formula. The red path shows the variable assignments 110 and 111. Determining the path and the outcome for every variable assignment results in the same truth table as seen in Example 3.10.

Given $n$ boolean variables and two boolean functions encoded as BDDs we can perform binary operations $\vee, \wedge$ on the BDDs in $O\left(N_{a} * N_{b}\right)$, where $N_{a}$ and $N_{b}$ are the number of nodes in the decision diagrams of the two functions. A decision diagram is a tree with $n$ levels, so $N_{a}=O\left(2^{n}\right)$ and $N_{b}=O\left(2^{n}\right)$. Therefore with $n$ boolean variables we can perform binary operations $\vee$ and $\wedge$ on them in $O\left(2^{2 n}\right)=O\left(m^{2}\right)$ where $m=2^{n}$ is the maximum set size that can be represented using $n$ variables 44, 5. The running time specifically depends on the size of the decision diagrams; in general if the boolean functions are simple then the size of the decision diagram is also small and operations can be performed quickly.

## 4. Problem statement

If we have an SPL with certain requirements that must hold for every product then we want to apply verification techniques to formally verify that indeed every product satisfies the requirements. We could verify every product individually, however verification is expensive in terms of computing time and the number of different products can grow large. Differences in behaviour between products might be very small; large parts of the different products might behave similar. In this thesis we aim to exploit commonalities between products to find a method that verifies an SPL in a more efficient way than verifying every product independently.

First we take a look at a method of modelling the behaviour of the different products in an SPL, namely featured transition systems (FTSs). An FTS extends an LTS to express variability, it does so by introducing features and products. Features are options that can be enabled or disabled for the system. A product is a feature assignments, i.e. a set of features that is enabled for that product. Not all products are valid; some features might be mutually exclusive for example. To express the relation between features one can use feature diagrams as explained in [9]. Feature diagrams offer a nice way of expressing which feature assignments are valid, however for simplicity we represent the collection of valid products simply as a set of feature assignments.

An FTS models the behaviour of multiple products by guarding transitions with boolean expressions over the features such that the transition is only enabled for products that satisfy the guard.
Let $\mathbb{B}(A)$ denote the set of all boolean expressions over the set of boolean variables $A$; a boolean expression is a function that maps a boolean assignment to either true of false. A boolean expression over a set of features is called a feature expression, it maps a feature assignment, i.e. a product, to either true or false. Given boolean expression $f$ and boolean variable assignment $p$ we write $p \models f$ if and only if $f$ is true for $p$ and write $p \not \vDash f$ otherwise. Boolean expression T denotes the boolean expression that is satisfied by all boolean assignments.

Definition 4.1 (9]). A featured transition system (FTS) is a tuple $M=\left(S, A c t\right.$, trans, $\left.s_{0}, N, P, \gamma\right)$, where:

- $S, A c t$, trans,$s_{0}$ are defined as in an LTS,
- $N$ is a non-empty set of features,
- $P \subseteq 2^{N}$ is a non-empty set of products, i.e. feature assignments, that are valid,
- $\gamma:$ trans $\rightarrow \mathbb{B}(N)$ is a total function, labelling each transition with a feature expression.

A transition $s \xrightarrow{a} s^{\prime}$ with $\gamma\left(s, a, s^{\prime}\right)=f$ is denoted by $s \xrightarrow{a \mid f} s^{\prime}$. FTSs are presented similarly as LTSs, the labels of the transition are expanded to represent both the action and the feature expression associated with it.

Example 4.1 (37). Consider a coffee machine that has two variants: in the first variant it takes a single coin and serves a standard coffee, in the second variant the machine either serves a standard coffee after a coin is inserted or it takes another coin after which it serves an xxl coffee. Note that there is no variant that only serves xxl coffees. We introduce two features: $\$$ which, if enabled, allows the coffee machine to serve xxl coffees and $€$ which, if enabled, allows the coffee machine to serve standard coffees. The valid products are: $\{\{€\},\{€, \$\}\}$. This FTS is depicted in Figure 4.1.

Figure 4.1: Coffee machine FTS $C$

An FTS expresses the behaviour of multiple products. The behaviour of a single product can be derived by simply removing all the transitions from the FTS for which the product does not satisfy the feature expression guarding the transition. We call this a projection.

Definition $4.2(9)$. The projection of $F T S M=\left(S\right.$, Act, trans, $\left.s_{0}, N, P, \gamma\right)$ onto product $p \in P$, denoted by $M_{\mid p}$, is the LTS $\left(S, A c t\right.$, trans $\left.^{\prime}, s_{0}\right)$, where trans ${ }^{\prime}=\{t \in$ trans $\mid p \models \gamma(t)\}$.

Example 4.2 ( 37$])$. The coffee machine example can be projected to its two products, which results in the LTSs in Figure 4.2.

(a) $C$ projected to the euro product: $C_{\mid\{€\}}$

(b) $C$ projected to the euro and dollar product: $C_{\mid\{€, \$\}}$

Figure 4.2: Projections of the coffee machine FTS

Problem statement Given an FTS $M$, that models the behaviour of an SPL, with products $P$ and modal $\mu$-calculus formula $\varphi$ we want to find the products in $P$ that satisfy $\varphi$. Formally we want to find set $P_{s}$ such that:

- for every $p \in P_{s}$ we have $M_{\mid p} \models \varphi$ and
- for every $p \in P \backslash P_{s}$ we have $M_{\mid p} \not \vDash \varphi$.

We aim to find $P_{s}$ in a way that utilizes the commonalities in behaviour between the different products.

## 5. Variability parity games

In the preliminaries we have seen how parity games can be used to check if a modal $\mu$-calculus formula is satisfied by an LTS. A parity game can be constructed such that it contains the information needed to determine if an LTS satisfies a modal $\mu$-calculus formula. We have also seen how an LTS can be extended with transition guards to model the behaviour of multiple LTSs. In this section we introduce variability parity games (VPGs); a VPG extends the definition of a parity game much like an FTS extends the definition of an LTS. Similar as to how an FTS expresses multiple LTSs does a VPG express multiple parity games. Moreover we introduce a way of creating VPGs such that every parity game it expresses contains the information needed to determine if a product in an FTS satisfies a modal $\mu$-calculus formula.

We extend parity games such that edges in the game are guarded. Instead of using features, feature expressions and products we choose a syntactically simpler representation and introduce configurations. A VPG has a set of configurations and is played for a single configuration. Edges are guarded by sets of configurations; if the VPG is played for a configuration that is in the guard set then the edge is enabled, otherwise it is disabled.

Definition 5.1. A variability parity game (VPG) is a tuple $\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$, where:

- $V, V_{0}, V_{1}, E$ and $\Omega$ are defined as in a parity game,
- $\mathfrak{C}$ is a non-empty finite set of configurations,
- $\theta: E \rightarrow 2^{\mathfrak{C}} \backslash \emptyset$ is a total function mapping every edge to a set of configurations guarding that edge.

VPGs are considered total when for every configuration $c \in \mathfrak{C}$ every vertex has at least one outgoing edge that admits configuration $c$. Formally, a VPG is total if and only if for all $v \in V$ :

$$
\bigcup\{\theta(v, w) \mid(v, w) \in E\}=\mathfrak{C}
$$

VPGs are depicted as parity games with labelled edges that represent the sets of configurations guarding them.

Example 5.1. Figure 5.1 shows an example of a total $V P G$ with configuration $\mathfrak{C}=\left\{c_{1}, c_{2}, c_{3}\right\}$.
A VPG can be played for a vertex-configuration pair. When playing a VPG for $v \in V$ and $c \in \mathfrak{C}$ we start by placing a token on vertex $v$. We proceed with the game similar as with a parity game, however player $\alpha$ can only move the token from $v \in V_{\alpha}$ to $w \in V$ if $(v, w) \in E$ and $c \in \theta(v, w)$. Similar as in a parity game this results in a path. Again the winner is determined by the highest priority occurring infinitely often in the path or, in case of a finite path, the winner is the opponent of the player that cannot make a move any more. Paths might be valid for some configurations but not valid for others, we call a path valid for configuration $c$ if and only if for every $i>0$ such that $\pi_{i}$ exists we have $\left(\pi_{i-1}, \pi_{i}\right) \in E$ and $c \in \theta\left(\pi_{i-1}, \pi_{i}\right)$.

Moves made by the players are again determined by strategies, however for different configurations for which the game is played different strategies might be needed. So we define a strategy not only for a player but also for a configuration. We define a strategy for player $\alpha$ and configuration $c \in \mathfrak{C}$ as a partial function $\sigma_{\alpha}^{c}: V^{*} V_{\alpha} \rightarrow V$ that maps a series of vertices ending with a vertex owned by player $\alpha$ to the next vertex such that for any $\sigma_{\alpha}^{c}\left(w_{0} \ldots w_{m}\right)=w$ we have $\left(w_{m}, w\right) \in E$ and $c \in \theta\left(w_{m}, w\right)$. A path $\pi$ conforms to strategy $\sigma_{\alpha}^{c}$ if for every $i>0$ such that $\pi_{i}$ exists and $\pi_{i-1} \in V_{\alpha}$ we have $\pi_{i}=\sigma_{\alpha}^{c}\left(\pi_{0} \pi_{1} \ldots \pi_{i-1}\right)$.

Figure 5.1: VPG with configurations $\mathfrak{C}=\left\{c_{1}, c_{2}, c_{3}\right\}$

A strategy $\sigma_{\alpha}^{c}$ is winning in configuration $c$ for player $\alpha$ from vertex $v$ if and only if $\alpha$ is the winner of every path valid for $c$ starting in $v$ that conforms to $\sigma_{\alpha}^{c}$. If such a strategy exists for player $\alpha$ and configuration $c$ starting from vertex $v$ then vertex $v$ is winning for player $\alpha$ and configuration $c$.

A VPG is solved if for every configuration $c$ the vertices are partitioned in two sets, namely $W_{0}^{c}$ and $W_{1}^{c}$, such that every vertex in $W_{\alpha}^{c}$ is winning for player $\alpha$ in configuration $c$. We call these sets the winning sets of a VPG.

We can create a parity game from a VPG by simply choosing configuration $c$ and removing all the edges that do not have $c$ in their guard set. We call this a projection.

Definition 5.2. The projection of $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ onto configuration $c \in \mathfrak{C}$, denoted by $G_{\mid c}$, is the parity game $\left(V, V_{0}, V_{1}, E^{\prime}, \Omega\right)$ where $E^{\prime}=\{e \in E \mid c \in \theta(e)\}$.

If a VPG is total then there is at least one outging edge for every vertex that admits configuration $c \in \mathfrak{C}$. This edge will be in the projection $G_{\mid c}$ so clearly when the VPG is total then its projections are also total.

A VPG contains multiple parity games, in fact playing a VPG $G$ for configuration $c$ is the same as playing the parity game $G_{\mid c}$ which we show in the following lemma's and theorem.

Lemma 5.1. Path $\pi$ is valid in $G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ for configuration $c$ if and only if path $\pi$ is valid in $G_{\mid c}=\left(V, V_{0}, V_{1}, E^{\prime}, \Omega\right)$.

Proof. Consider path $\pi$ that is valid in $G$ for configuration $c$. For every $i>0$ we have $\left(\pi_{i-1}, \pi_{i}\right) \in$ $E$ and $c \in \theta\left(\pi_{i-1}, \pi_{i}\right)$. Using the projection definition (Definition 5.2) we can conclude that $\left(\pi_{i-1}, \pi_{1}\right) \in E^{\prime}$ making the path valid in $G_{\mid c}$.

Consider path $\pi$ that is valid in $G_{\mid c}$. For every $i>0$ we have $\left(\pi_{i-1}, \pi_{i}\right) \in E^{\prime}$. Given the projection
definition we find that because $\left(\pi_{i-1}, \pi_{i}\right) \in E^{\prime}$ we must have $\left(\pi_{i-1}, \pi_{i}\right) \in E$ and $c \in \theta\left(\pi_{i-1}, \pi_{i}\right)$. This makes the path valid in $G$ for configuration $c$.

Lemma 5.2. Any strategy $\sigma_{\alpha}^{c}$ for player $\alpha$ and configuration $c \in \mathfrak{C}$ in $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ is also a strategy in $G_{\mid c}$ for player $\alpha$ and any strategy $\sigma_{\alpha}$ for player $\alpha$ in $G_{\mid c}$ is also a strategy in $G$ for player $\alpha$ and configuration $c$.

Proof. The same reasoning as in Lemma 5.1 can be applied to prove this lemma.
Theorem 5.3. Winning sets $\left(W_{0}^{c}, W_{1}^{c}\right)$ of $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ played for configuration $c \in \mathfrak{C}$ are equal to winning sets $\left(Q_{0}, Q_{1}\right)$ of parity game $G_{\mid c}$.

Proof. Let $v \in W_{\alpha}^{c}$ for some $\alpha \in\{0,1\}$. There exists a strategy $\sigma_{\alpha}^{c}$ in VPG $G$ for player $\alpha$ and configuration $c$ such that any valid path starting in $v$ and conforming to $\sigma_{\alpha}^{c}$ is winning for player $\alpha$. As shown in Lemma 5.2, $\sigma_{\alpha}^{c}$ is also a strategy for player $\alpha$ in $G_{\mid c}$. Any valid path starting in $v$ in game $G$ played for configuration $c$ is also valid in game $G$ as shown in Lemma 5.1, additionally any path valid in $G_{\mid c}$ is also valid in $G$ played for $c$. Assume there is a valid path in $G_{\mid c}$ that conforms to $\sigma_{\alpha}^{c}$ starting from $v$ that is not won by player $\alpha$. This path is also valid in $G$ played for configuration $c$ and conforming to $\sigma_{\alpha}^{c}$ which contradicts $v \in W_{\alpha}^{c}$, therefore no such path exists and strategy $\sigma_{\alpha}^{c}$ is winning for player $\alpha$ from $v$ in parity game $G_{\mid c}$, hence $v \in Q_{\alpha}$.

Let $v \in Q_{\alpha}$ for some $\alpha \in\{0,1\}$. There exists a strategy $\sigma_{\alpha}$ in parity game $G_{\mid c}$ for player $\alpha$ such that any valid path starting in $v$ and conforming to $\sigma_{\alpha}$ is winning for player $\alpha$. Using Lemma 5.2 we find that $\sigma_{\alpha}$ is a strategy in game $G$ for player $\alpha$ and configuration $c$. Assume there is a valid path in $G$ for $c$ that conforms to $\sigma_{\alpha}$ starting from $v$ that is not won by player $\alpha$. This path is also valid in $G_{\mid c}$ and conforming to $\sigma_{\alpha}$ which contradicts $v \in Q_{\alpha}$, therefore no such path exists and strategy $\sigma_{\alpha}$ is winning for player $\alpha$ and configuration $c$ from $v$ in VPG $G$, hence $v \in W_{\alpha}^{c}$.

Parity games have a unique winner for every vertex, from Theorem 5.3 we can conclude that a VPG played for a configuration also has a unique winner for every vertex. Moreover since it is decidable who wins a vertex in a parity game it is also decidable who wins a vertex in a VPG for configuration $c$. Finally, in a parity game there exists a positional strategy for player $\alpha$ that is winning for all the vertices won by player $\alpha$ in the game. In Theorem 5.3 we argued that a strategy that is winning for player $\alpha$ starting in vertex $v$ in a projection of $G$ onto $c$ is also winning in $G$ for player $\alpha$ and configuration $c$ starting in vertex $v$. So we can conclude that VPGs are also positionally determined and we can consider a strategy for player $\alpha$ and configuration $c$ as a function $\sigma_{\alpha}^{c}: V_{\alpha} \rightarrow V$.

Example 5.2. Consider the VPG in Figure 5.1. When playing the game for vertex $v_{5}$ and configuration $c_{1}$ we can define strategy

$$
\sigma_{1}^{c_{1}}=\left\{v_{5} \mapsto v_{7}, v_{7} \mapsto v_{6}, v_{6} \mapsto v_{7}, \ldots\right\}
$$

This always results in the path $v_{5}\left(v_{7} v_{6}\right)^{\omega}$ where the highest priority occurring infinitely often is 3, so player 1 wins. Since this is the only valid path vertex $v_{5}$ is won by player 1 in configuration $c_{1}$.

If the game is played for vertex $v_{5}$ and configuration $c_{2}$ the strategy $\sigma_{1}^{c_{1}}$ is not valid because the edge $\left(v_{5}, v_{7}\right)$ is not enabled. For player 0 we can define strategy

$$
\sigma_{0}^{c_{2}}=\left\{v_{2} \mapsto v_{4}, v_{4} \mapsto v_{1}, \ldots\right\}
$$

Player 1 can only play from $v_{5}$ to $v_{2}$ so the only path that conforms to $\sigma_{0}^{c_{2}}$ is $v_{5}\left(v_{2} v_{4} v_{1}\right)^{\omega}$, which is winning for player 0 . So vertex $v_{5}$ is won by player 0 in configuration $c_{2}$.

If the game is played for vertex $v_{5}$ and configuration $c_{3}$ then player 0 can win $v_{5}$ using the strategy

$$
\sigma_{0}^{c_{3}}=\left\{v_{2} \mapsto v_{6}, v_{3} \mapsto v_{2}, v_{4} \mapsto v_{5}\right\}
$$

Player 1 can play to $v_{2}$ or $v_{7}$. If the play goes to $v_{2}$ then player 0 plays to $v_{6}$ from where play can only go to $v_{3}$ and $v_{2}$ next. We get path $v_{5}\left(v_{2} v_{6} v_{3}\right)^{\omega}$, which is won by player 0 . If player 1 plays to $v_{7}$ then play can only go to $v_{4}$ where player 0 plays to $v_{5}$. If play stays in this loop then player 0 wins because the highest priority occurring infinitely often is 2. If play eventually goes to $v_{2}$ then player 0 wins as well.

### 5.1 Verifying featured transition systems

Given an LTS and a modal $\mu$-calculus formula we can construct a parity game such that solving this parity game tells us if the LTS satisfies the formula. Similarly we can construct a VPG from an FTS and a modal $\mu$-calculus in such a way that solving the VPG tells us what products satisfy the formula.

We create a VPG from an FTS by choosing the set of configurations to be equal to the set of products in the FTS. The game graph is created similar as to how a parity game is created from an LTS. Finally transition guards from the FTS are translated into guard sets for the VPG.

Definition 5.3. $\operatorname{FTS2VPG}(M, \varphi)$ converts $F T S M=\left(S, A c t\right.$, trans, $\left.s_{0}, N, P, \gamma\right)$ and closed formula $\varphi$ to $V P G\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$.
The set of configurations is equal to the set of products, i.e. $\mathfrak{C}=P$.
Vertices are created for every state with every formula in the Fischer-Ladner closure of $\varphi$. We define the set of vertices:

$$
V=S \times F L(\varphi)
$$

The following table shows the owners, successors with edge guards and priorities of vertices. We write $w \mid C$ as a successor of $v$ to denote that there is an edge $(v, w) \in E$ such that the edge is guarded by set $C \subseteq \mathfrak{C}$, i.e. $\theta(v, w)=C$.

| Vertex | Owner | Successor $\mid$ guard set | Priority |
| :--- | :--- | :--- | :--- |
| $(s, \perp)$ | 0 |  | 0 |
| $(s, \top)$ | 1 |  | 0 |
| $\left(s, \psi_{1} \vee \psi_{2}\right)$ | 0 | $\left(s, \psi_{1}\right) \mid \mathfrak{C}$ and $\left(s, \psi_{2}\right) \mid \mathfrak{C}$ | 0 |
| $\left(s, \psi_{1} \wedge \psi_{2}\right)$ | 1 | $\left(s, \psi_{1}\right) \mid \mathfrak{C}$ and $\left(s, \psi_{2}\right) \mid \mathfrak{C}$ | 0 |
| $(s,\langle a\rangle \psi)$ | 0 | $\left(s^{\prime}, \psi\right) \mid\{c \in \mathfrak{C} \mid c \models g\}$ for every $s \xrightarrow{a \mid g} s^{\prime}$ | 0 |
| $(s,[a] \psi)$ | 1 | $\left(s^{\prime}, \psi\right) \mid\{c \in \mathfrak{C} \mid c \models g\}$ for every $s \xrightarrow{a \mid g} s^{\prime}$ | 0 |
| $(s, \mu X . \psi)$ | 1 | $(s, \psi[X:=\mu X . \psi]) \mid \mathfrak{C}$ | $2\lfloor\operatorname{adepth}(X) / 2\rfloor+1$ |
| $(s, \nu X . \psi)$ | 1 | $(s, \psi[X:=\nu X . \psi]) \mid \mathfrak{C}$ | $2\lfloor\operatorname{adepth}(X) / 2\rfloor$ |

Since the Fischer-Ladner formulas are closed we never get a vertex $(s, X)$.

Similar to a parity game, a VPG can be made total by creating sink vertices $l_{0}$ and $l_{1}$ with priority 1 and 0 respectively and each having an edge to itself with guard set $\mathfrak{C}$. When the VPG is played for configuration $c$ and the token ends up in $l_{\alpha}$ then clearly player $\alpha$ looses. We make a VPG total by adding vertices $l_{0}$ and $l_{1}$ and adding an edge from every vertex $v \in V_{\alpha}$ that has $\bigcup\{\theta(v, w) \mid(v, w) \in E\} \neq \mathfrak{C}$ to $l_{\alpha}$ with guard set $\mathfrak{C} \backslash \bigcup\{\theta(v, w) \mid(v, w) \in E\}$. Any vertex $v_{\alpha}$ where player $\alpha$ could not have made a move in the original game played for configuration $c$ now has an edge admitting $c$ to $l_{\alpha}$ where player $\alpha$ still looses. An edge admitting $c$ is only added if there was no outgoing edge admitting $c$ so the winner of vertex $v$ for configuration $c$ in the original game is the same as in the total game.

Example 5.3. Consider FTS M, as shown in Figure 5.2, that has features $f$ and $g$ and products $\{\emptyset,\{f\},\{f, g\}\}$. Modal $\mu$-calculus formula $\varphi=\mu X .([a] X \vee\langle b\rangle \top)$ expresses that on any path reached by a's we can eventually do a b action. This holds true for product $\{\emptyset\}$ because $s_{1}$ can only go to $s_{2}$ where $b$ can always be done. For product $\{f\}$ this does not hold because once in $s_{1}$ it is possible to stay in $s_{1}$ indefinitely through an a transition. For product $\{f, g\}$ the formula does hold because we can indeed stay in $s_{1}$ indefinitely, however from $s_{1}$ we can always do $a b$ step.
Figure 5.3 shows the $V P G$ resulting from $\operatorname{FTS2VPG}(M, \varphi)$ made total using sink vertices $l_{0}$ and $l_{1}$. Products $\{\emptyset\},\{f\},\{f, g\}$ are depicted as configurations $c_{1}, c_{2}, c_{3}$ respectively.

Figure 5.2: FTS $M$

Figure 5.3: Total VPG created by FTS2VPG with $\phi=[a] X \vee\langle b\rangle \top$

In order to prove that solving a VPG created by FTS2VPG can be used to model check an FTS we inspect the relations we have seen between FTSs, LTSs, parity games and VPGs. Given FTS
$M$ and formula $\varphi$ we can project $M$ onto a product to create an LTS and create a parity game from the resulting LTS and $\varphi$ using $\operatorname{LTS2PG}$. Alternatively we can create a VPG from $M$ and $\varphi$ using FTS2VPG which can be projected onto a configuration to get a parity game. These different transformations are shown in the following diagram, where $\Pi_{p}$ depicts a projection onto product $p$ or configuration $p$ :

In the following lemma we prove that in fact parity game $G$ and $\hat{G}_{\mid p}$ are identical.
Lemma 5.4. Given $F T S M=\left(S\right.$, Act, trans, $\left.s_{0}, N, P, \gamma\right)$, closed modal $\mu$-calculus formula $\varphi$ and product $p \in P$ it holds that parity games $\operatorname{LTS2PG}\left(M_{\mid p}, \varphi\right)$ and $\operatorname{FTS2VPG}(M, \varphi)_{\mid p}$ are identical.

Proof. Let $\hat{G}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}, \hat{\Omega}, \mathfrak{C}, \theta\right)$ be the VPG created from $\operatorname{FTS2VPG}(M, \varphi)$ and let $G=$ $\left(V, V_{0}, V_{1}, E, \Omega\right)$ be the parity game created from $\operatorname{LTS2P} G\left(M_{\mid p}, \varphi\right)$. Let the projection of $\hat{G}$ onto $p$ (using Definition 5.2 be the parity game $\hat{G}_{\mid p}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}^{\prime}, \hat{\Omega}\right)$. We prove that $\hat{G}_{\mid p}=G$.
First observe that when an FTS is projected onto a product (using Definition 4.2) the FTS has the same states as the projection, we find that $M$ has the same states as $M_{\mid p}$. The vertices created by LTS2PG and FTS2VPG rely only on the formula and the states in the LTS and FTS respectively. Similarly the owner and priority of these vertices is only determined by the states and the formula. Given that $M$ and $M_{\mid p}$ have the same states we find that $\hat{V}=V, \hat{V}_{0}=V_{0}$, $\hat{V}_{1}=V_{1}$ and $\hat{\Omega}=\Omega$.
We are left with showing $\hat{E}^{\prime}=E$ in order to conclude $\hat{G}_{\mid p}=G$. Consider vertex $v$, we distinguish two cases.

Let $v=(s,\langle a\rangle \psi)$ or $v=(s,[a] \psi)$. If $v$ has a successor to $\left(s^{\prime}, \psi\right)$ in $G$ then we have $s \xrightarrow{a} s^{\prime}$ in $M_{\mid p}$ and therefore $s \xrightarrow{a \mid f} s^{\prime}$ with $p \models f$ in $M$. Using the FTS2VPG definition we find that vertex $v$ in $\hat{G}$ has successor $\left(s^{\prime}, \psi\right)$ with a guard containing $p$. Since $p$ is in the guard set we also find this successor in the projection $\hat{G}_{\mid p}$.

If $v$ has a successor to $\left(s^{\prime}, \psi\right)$ in $\hat{G}_{\mid p}$ then in $\hat{G}$ the edge from $v$ to $\left(s^{\prime}, \psi\right)$ also exists and the set guarding it contains $p$. In $M$ we find $s \xrightarrow{a \mid g} s^{\prime}$ with $p \models g$, therefore we find $s \xrightarrow{a} s^{\prime}$ in $M_{\mid p}$. Using the LTS2PG definition we find that vertex $v$ in $G$ has successor $\left(s^{\prime}, \psi\right)$.

Let $v \neq(s,\langle a\rangle \psi)$ and $v \neq(s,[a] \psi)$. Any successor of $v$ created by LTSZPG does not depend on the LTS but only on the formula. Similarly any successor of $v$ created by FTS2VPG does not depend on the FTS and has guard set $\mathfrak{C}$. The two definitions create the same successors for $v$, so the successors in games $G$ and $\hat{G}$ are the same. Since the guard sets of these successors are always $\mathfrak{C}$ the successors are also the same in $\hat{G}_{\mid p}$.
We have proven $\hat{E}^{\prime}=E$ and therefore $\hat{G}_{\mid p}=G$.
Using this lemma we get the following diagram showing the relation between FTSs, LTSs, parity games and VPGs.

We know from existing theory that solving a parity game constructed using LTS2PG can be used to model check an LTS, furthermore we have seen that the winning sets of a VPG for configuration $c$ are equal to the winning sets of that VPG projected onto $c$. Given these facts and the lemma above we can prove that VPGs can be used to model check FTSs.
Theorem 5.5. Given:

- $F T S M=\left(S, A c t\right.$, trans $\left., s_{0}, N, P, \gamma\right)$,
- closed modal $\mu$-calculus formula $\varphi$,
- product $p \in P$ and
- state $s \in S$
it holds that $\left(M_{\mid p}, s\right) \models \varphi$ if and only if $(s, \varphi) \in W_{0}^{p}$ in $\operatorname{FTS2VPG}(M, \varphi)$.
Proof. Assume $\left(M_{\mid p}, s\right) \models \varphi$, using the relation between LTSs and parity games (Theorem 3.2p we find that vertex $(s, \varphi)$ in parity game $\operatorname{LTS} 2 P G\left(M_{\mid p}, \varphi\right)$ is won by player 0 . Using Lemma 5.4 we find that vertex $(s, \varphi)$ is also in game $\operatorname{FTS2VPG}(M, \varphi)_{\mid p}$ and is also won by player 0 . Using Theorem 5.3 we find that the winning sets of a VPG for configuration $c$ are the same as the winning sets of the projection of the VPG onto $c$. We find that vertex $(s, \varphi)$ is winning in game $\operatorname{FTS2VPG}(M, \varphi)$ for configuration $p$, hence $(s, \varphi) \in W_{0}^{p}$.
Similarly if $\left(M_{\mid p}, s\right) \not \vDash \varphi$ vertex $(s, \varphi)$ is won by player 1 in parity game $\operatorname{LTS2PG}\left(M_{\mid p}, \varphi\right)$ and we get $(s, \varphi) \notin W_{0}^{p}$.

Example 5.4. Again consider Example 5.3. We argued that $M$ satisfies $\varphi$ for products $\{\emptyset\}$ and $\{f, g\}$. We see, in the VPG in Figure 5.3, that $\left(s_{1}, \mu X .([a] X \vee\langle b\rangle \top)\right)$ is indeed winning for player 0 when played for $\{\emptyset\}=c_{1}$ using the strategy

$$
\sigma_{0}^{c_{1}}=\left\{\left(s_{1},[a](\mu X . \phi) \vee\langle b\rangle \top\right) \mapsto\left(s_{1},[a](\mu X . \phi)\right),\left(s_{2},[a](\mu X . \phi) \vee\langle b\rangle \top\right) \mapsto\left(s_{2},\langle b\rangle \top\right), \ldots\right\}
$$

Using this strategy play always ends up in $l_{1}$, which is winning for player 0.
For product $\{f\}=c_{2}$ player 1 wins using strategy

$$
\sigma_{1}^{c_{2}}=\left\{\left(s_{1},[a](\mu X . \phi)\right) \mapsto\left(s_{1}, \mu X . \phi\right), \ldots\right\}
$$

Using this strategy we either infinitely often visit $\left(s_{1}, \mu X . \psi\right)$ in which case player 1 wins or player 0 can decide to play to $\left(s_{1},\langle b\rangle \top\right)$ in which case play ends in $l_{0}$ and player 1 wins.

For product $\{f, g\}=c_{3}$ player 0 wins using strategy

$$
\sigma_{0}^{c_{3}}=\left\{\left(s_{1},[a](\mu X . \phi) \vee\langle b\rangle \top\right) \mapsto\left(s_{1},\langle b\rangle \top\right),\left(s_{1},\langle b\rangle \top\right) \mapsto\left(s_{1}, \top\right), \ldots\right\}
$$

Using this strategy player 0 can prevent the path from infinitely often visiting ( $s_{1}, \mu X . \psi$ ) by playing to $\left(s_{1},\langle b\rangle \top\right)$ and to $\left(s_{1}, \top\right)$ next, which brings the play in $l_{1}$ winning it for player 0 .

We conclude by visualizing the verification of an FTS in Figure 5.4 .

Figure 5.4: FTS verification using VPG

## 6. Solving variability parity games

In this section we inspect methods so solve VPGs, for convenience we only consider total VPGs. We distinguish two general approaches for solving VPGs. The first approach is to simply project the VPG to the different configurations and solve all the resulting parity games independently; we call this independently solving a VPG. Existing parity game algorithms can be used in this approach. Alternatively, we solve the VPG collectively where a VPG is solved in its entirety and similarities between the configurations are used to improve performance.

As shown in Chapter 5 the projections of VPGs originating from an FTS and a modal $\mu$-calculus formula are identical to the parity games constructed from an projections of the FTS and a model $\mu$-calculus formula. Therefore, independently solving a VPG is the same as model checking all the different products in an FTS independently

We aim to solve VPGs originating from model verification problems, such VPGs generally have certain properties that a random VPG might not have. In general (V)PGs originating from model verification problems have a relatively low number of distinct priorities compared to the number of vertices, this is because new priorities are only introduced when fixed points are nested in the $\mu$-calculus formula. Furthermore the transition guards of FTSs are boolean formulas over features. In general these formulas will be quite simple, specifically excluding or including a small number of features.

### 6.1 Recursive algorithm for variability parity games

We can use the original Zielonka's recursive algorithm to solve VPGs by creating one big parity game of a VPG through a process we introduce called unification. This parity game can be solved using the original recursive algorithm. However, we introduce a way of representing this parity game that potentially increases performance and exploits commonalities between different configurations in the VPG.

### 6.1.1 Unified parity games

We can create a parity game from a VPG by taking all the projections of the VPG, which are parity games, and combining them into one parity games by taking the union of them. We call the resulting parity games the unification of the VPG. A parity game that is the result of a unification is called a unified parity game. Also any subgame of it will be called a unified parity games. A unified parity game always has a VPG from which it originated.
Definition 6.1. Given $V P G \hat{G}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}, \hat{\Omega}, \mathfrak{C}, \theta\right)$ we define the unification of $\hat{G}$, denoted by $\hat{G}_{\downarrow}$, as

$$
\hat{G}_{\downarrow}=\biguplus_{c \in \mathfrak{C}} \hat{G}_{\mid c}
$$

where the disjoint union of two parity games is defined as

$$
\left(V, V_{0}, V_{1}, E, \Omega\right) \uplus\left(V^{\prime}, V_{0}^{\prime}, V_{1}^{\prime}, E^{\prime}, \Omega^{\prime}\right)=\left(V \uplus V^{\prime}, V_{0} \uplus V_{0}^{\prime}, V_{1} \uplus V_{1}^{\prime}, E \uplus E^{\prime}, \Omega \uplus \Omega^{\prime}\right)
$$

and the disjoint union of functions $\Omega: V \rightarrow \mathbb{N}$ and $\Omega^{\prime}: V^{\prime} \rightarrow \mathbb{N}$ is defined as

$$
\left(\Omega \uplus \Omega^{\prime}\right)(v)= \begin{cases}\Omega(v) & \text { if } v \in V \\ \Omega^{\prime}(v) & \text { if } v \in V^{\prime}\end{cases}
$$

In this section we use the hat decoration $(\hat{G}, \hat{V}, \hat{E}, \hat{\Omega}, \hat{W})$ when referring to a VPG and use no hat decoration when referring to a (unified) parity game.

Every vertex in unified parity game $\hat{G}_{\downarrow}$ originates from a configuration and an original vertex. Therefore we can consider every vertex in a unification as a vertex-configuration pair, i.e. $V=$ $\mathfrak{C} \times \hat{V}$. We can consider edges in a unification similarly, so $E \subseteq(\mathfrak{C} \times \hat{V}) \times(\mathfrak{C} \times \hat{V})$. Note that edges do not cross configurations, so for every $\left((c, \hat{v}),\left(c^{\prime}, \hat{v}^{\prime}\right)\right) \in E$ we have $c=c^{\prime}$. We call set $\hat{V}$ the origin vertices of a unified parity game.
Example 6.1. Figure 6.1 shows a $V P G$ and its the unification.

(a) VPG with 2 configurations

(b) Unified parity game, created by unifying the two projections

Figure 6.1: A VPG with its corresponding unified parity game

Clearly solving unified parity game $\hat{G}_{\downarrow}$ solves all the projections of VPG $\hat{G}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}, \hat{E}, \mathfrak{C}, \theta\right)$. Theorem 5.3 shows that if we solve all the projections of a VPG we have solved the VPG. So solving $\hat{G}_{\downarrow}$ also solves $\hat{G}$. Consider winning sets $\left(W_{0}^{c}, W_{1}^{c}\right)$ for $\hat{G}$ played for configuration $c$ and winning sets $\left(Q_{0}, Q_{1}\right)$ for $\hat{G}_{\downarrow}$. Using Theorem 5.3 we find the following relation:

$$
W_{\alpha}^{c}=\left\{\hat{v} \mid(c, \hat{v}) \in Q_{\alpha}\right\}
$$

## Projections and totality

A unified parity game can be projected onto a configuration to get one of the parity games from which it is the union. This is very similar to the projection of a VPG onto a configuration. Specifically we have for VPG $\hat{G}$ and configuration $c$ that $\hat{G}_{\mid c}=\left(\hat{G}_{\downarrow}\right)_{\mid c}$. Eventhough these definitions are so similar we do need to introduce the projection of unified parity games to be able to reason about projections of subgames of unified parity games.

Definition 6.2. The projection of unified parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ to configuration $c$, denoted as $G_{\mid c}$, is the parity game $\left(V^{\prime}, V_{0}^{\prime}, V_{1}^{\prime}, E^{\prime}, \Omega\right)$ such that:

- $V^{\prime}=\{\hat{v} \mid(c, \hat{v}) \in V\}$,
- $V_{0}^{\prime}=\left\{\hat{v} \mid(c, \hat{v}) \in V_{0}\right\}$,
- $V_{1}^{\prime}=\left\{\hat{v} \mid(c, \hat{v}) \in V_{1}\right\}$ and
- $E^{\prime}=\{(\hat{v}, \hat{w}) \mid((c, \hat{v}),(c, \hat{w})) \in E\}$

One of the properties of a parity game is its totality; a game is total if every vertex has at least one outgoing vertex. The VPGs we consider are also total, meaning that every vertex has, for every configuration $c \in \mathfrak{C}$, at least one outgoing edge admitting $c$. Because VPGs are total their unifications are also total. Since edges in a unified parity game do not cross configurations the projection of a total unified parity game is also total.

### 6.1.2 Solving unified parity games

Since unified parity games are total they can be solved using Zielonka's recursive algorithm. The recursive algorithm revolves around the attractor operation. Consider the example presented in Figure 6.1. Vertices with the highest priority are

$$
\left\{\left(c_{1}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{1}\right)\right\}
$$

attracting these for player 0 gives the set

$$
\begin{array}{r}
\left\{\left(c_{1}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{1}\right),\right. \\
\left(c_{1}, \hat{v}_{2}\right),\left(c_{2}, \hat{v}_{2}\right), \\
\left.\left(c_{2}, \hat{v}_{3}\right)\right\}
\end{array}
$$

The algorithm tries to attract vertices $\left(c_{1}, \hat{v}_{2}\right)$ and $\left(c_{2}, \hat{v}_{2}\right)$ because they have edges to $\left\{\left(c_{1}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{1}\right)\right\}$. So the algorithm, in this case, asks the questions: "Can vertices ( $c_{1}, \hat{v}_{2}$ ) and ( $c_{2}, \hat{v}_{2}$ ) be attracted?" We could also ask the question: "For which configurations can we attract origin vertex $\hat{v}_{2}$ ?" Since the vertices in unified parity games are pairs of configurations and origin vertices we can, instead of considering vertices individually, consider origin vertices and try to attract as many configurations as possible for each origin vertex. This is the idea of the collective recursive algorithm for VPGs we present next. We introduce a way of efficiently representing unified parity games and an algorithm that behaves the same as the original recursive algorithm but uses the modified representation. Using this representation we can create an attractor set algorithm that tries to attract as many configurations per origin vertex as possible instead of trying to attract each vertex individually.

In VPGs originating from FTSs a large number of edges admit all configurations (as is evident from Definition 5.3. Furthermore the sets that do not admit all configurations originate from the boolean formulas guarding transitions in the FTS. As argued before, these sets will most likely admit many configurations, because in many cases the boolean function will simply include or exclude a small number of features. Because of these two facts we hypothesise that VPGs originating from FTSs have edge guard sets that are relatively large (i.e. admit many of the configurations) and therefore we can attract many configurations at the same time per origin vertex.

### 6.1.3 Representing unified parity games

Unified parity games have a specific structure because they are the union of parity games that have the same vertices with the same owner and priority. Because they have the same priority we do not actually need to create a new function that is the unification of all the projections, we can simply use the original priority assignment function because the following relation holds:

$$
\Omega(c, \hat{v})=\hat{\Omega}(\hat{v})
$$

Similarly we can use the original partition sets $\hat{V}_{0}$ and $\hat{V}_{1}$ instead of having the new partition $V_{0}$ and $V_{1}$ because the following relations hold:

$$
\begin{aligned}
& (c, \hat{v}) \in V_{0} \Longleftrightarrow \hat{v} \in \hat{V}_{0} \\
& (c, \hat{v}) \in V_{1} \Longleftrightarrow \hat{v} \in \hat{V}_{1}
\end{aligned}
$$

So instead of considering unified parity game $\left(V, V_{0}, V_{1}, E, \Omega\right)$ we consider $\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$.
Next we consider how we represent vertices and edges in a unified parity game. A set $X \subseteq(\mathfrak{C} \times \hat{V})$ can be represented as a total function $X^{\lambda}: \hat{V} \rightarrow 2^{\mathfrak{C}}$. The set $X$ and function $X^{\lambda}$ are equivalent, denoted by the operator $={ }_{\lambda}: 2^{\mathfrak{C} \times \hat{V}} \times\left(\hat{V} \rightarrow 2^{\mathfrak{C}}\right) \rightarrow \mathbb{B}$, such that

$$
X={ }_{\lambda} X^{\lambda} \text { if and only if }(c, \hat{v}) \in X \Longleftrightarrow c \in X^{\lambda}(\hat{v}) \text { for all } c \in \mathfrak{C} \text { and } \hat{v} \in \hat{V}
$$

We can also represent edges as a total function $E^{\lambda}: \hat{E} \rightarrow 2^{\mathfrak{C}}$. The set $E$ and function $E^{\lambda}$ are equivalent, denoted by the operator $={ }_{\lambda} 2^{(\mathfrak{C} \times \hat{V}) \times(\mathfrak{C} \times \hat{V})} \times\left(\hat{E} \rightarrow 2^{\mathfrak{C}}\right) \rightarrow \mathbb{B}$, such that:

$$
E={ }_{\lambda} E^{\lambda} \text { if and only if }\left((c, \hat{v}),\left(c, \hat{v}^{\prime}\right)\right) \in E \Longleftrightarrow c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \text { for all } c \in \mathfrak{C} \text { and } \hat{v}, \hat{v}^{\prime} \in \hat{V}
$$

We use the $=_{\lambda}$ operator to indicate that a set and a function represent the same vertices or edges. For convenience of notation we denote equality for edges and vertices both using the $=_{\lambda}$ operator. We define $\lambda^{\emptyset}$ to be the function that maps every element to $\emptyset$, clearly $\lambda^{\emptyset}={ }_{\lambda} \emptyset$.

We call using a set of pairs to represent vertices and edges a set-wise representation and using functions a function-wise representation.
Example 6.2. We consider a few examples of (sub)games and show their set-wise and functionwise representation. First reconsider the following unified parity game.

This game can be represented set-wise:

$$
\begin{aligned}
V=\{ & \left.\left(c_{1}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{1}\right),\left(c_{1}, \hat{v}_{2}\right),\left(c_{2}, \hat{v}_{2}\right),\left(c_{1}, \hat{v}_{3}\right),\left(c_{2}, \hat{v}_{3}\right)\right\} \\
E= & \left\{\left(\left(c_{1}, \hat{v}_{1}\right),\left(c_{1}, \hat{v}_{1}\right)\right),\left(\left(c_{1}, \hat{v}_{1}\right),\left(c_{1}, \hat{v}_{2}\right)\right),\left(\left(c_{1}, \hat{v}_{2}\right),\left(c_{1}, \hat{v}_{1}\right)\right),\right. \\
& \left(\left(c_{1}, \hat{v}_{2}\right),\left(c_{1}, \hat{v}_{3}\right)\right),\left(\left(c_{1}, \hat{v}_{3}\right),\left(c_{1}, \hat{v}_{1}\right)\right),\left(\left(c_{1}, \hat{v}_{3}\right),\left(c_{1}, \hat{v}_{3}\right)\right), \\
& \left.\left(\left(c_{2}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{2}\right)\right),\left(\left(c_{2}, \hat{v}_{2}\right),\left(c_{2}, \hat{v}_{1}\right)\right),\left(\left(c_{2}, \hat{v}_{2}\right),\left(c_{2}, \hat{v}_{3}\right)\right),\left(\left(c_{2}, \hat{v}_{3}\right),\left(c_{2}, \hat{v}_{2}\right)\right)\right\}
\end{aligned}
$$

and function-wise:

$$
\left.\left.\begin{array}{rl}
V^{\lambda}= & \left\{\hat{v}_{1} \mapsto\left\{c_{1}, c_{2}\right\}, \hat{v}_{2} \mapsto\left\{c_{1}, c_{2}\right\}, \hat{v}_{3} \mapsto\left\{c_{1}, c_{2}\right\}\right\} \\
E^{\lambda}=\{ & \left\{\left(\hat{v}_{1}, \hat{v}_{2}\right) \mapsto\left\{c_{1}, c_{2}\right\},\left(\hat{v}_{2}, \hat{v}_{1}\right) \mapsto\left\{c_{1}, c_{2}\right\},\left(\hat{v}_{2}, \hat{v}_{3}\right) \mapsto\left\{c_{1}, c_{2}\right\},\right. \\
& \left(\hat{v}_{1}, \hat{v}_{1}\right) \mapsto\left\{c_{1}\right\} \\
& \left(\hat{v}_{3}, \hat{v}_{1}\right) \\
& \mapsto\left\{c_{1}\right\}, \\
& \left(\hat{v}_{3}, \hat{v}_{2}\right)
\end{array}>\left\{c_{2}\right\},\right\}\left(\hat{v}_{3}, \hat{v}_{3}\right) \mapsto\left\{c_{1}\right\}\right\}, ~ \$
$$

Consider the following subgame:

This subgame can be represented set-wise:

$$
\begin{aligned}
V=\{ & \left.\left(c_{1}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{2}\right)\right\} \\
E=\{ & \left\{\left(\left(c_{1}, \hat{v}_{1}\right),\left(c_{1}, \hat{v}_{1}\right)\right)\right. \\
& \left.\left(\left(c_{2}, \hat{v}_{1}\right),\left(c_{2}, \hat{v}_{2}\right)\right),\left(\left(c_{2}, \hat{v}_{2}\right),\left(c_{2}, \hat{v}_{1}\right)\right)\right\}
\end{aligned}
$$

and function-wise:

$$
\begin{aligned}
V^{\lambda}=\{ & \left.\hat{v}_{1} \mapsto\left\{c_{1}, c_{2}\right\}, \hat{v}_{2} \mapsto\left\{c_{2}\right\}, \hat{v}_{3} \mapsto \emptyset\right\} \\
E^{\lambda}=\{ & \left(\hat{v}_{1}, \hat{v}_{2}\right) \mapsto\left\{c_{2}\right\},\left(\hat{v}_{2}, \hat{v}_{1}\right) \mapsto\left\{c_{2}\right\},\left(\hat{v}_{2}, \hat{v}_{3}\right) \mapsto \emptyset, \\
& \left(\hat{v}_{1}, \hat{v}_{1}\right) \mapsto\left\{c_{1}\right\}, \\
& \left(\hat{v}_{3}, \hat{v}_{1}\right) \mapsto \emptyset \\
& \left.\left(\hat{v}_{3}, \hat{v}_{2}\right) \mapsto \emptyset\right\}
\end{aligned}
$$

Finally consider an empty subgame which we can represent set-wise:

$$
V=\emptyset, E=\emptyset
$$

and function-wise:

$$
V^{\lambda}=\lambda^{\emptyset}, E^{\lambda}=\lambda^{\emptyset}
$$

We define the union of two functions $X^{\lambda}: \hat{V} \rightarrow 2^{\mathfrak{C}}$ and $Y^{\lambda}: \hat{V} \rightarrow 2^{\mathfrak{C}}$ point-wise:

$$
\left(X^{\lambda} \cup Y^{\lambda}\right)(\hat{v})=X^{\lambda}(\hat{v}) \cup Y^{\lambda}(\hat{v})
$$

We also define the subset or equal relation point-wise:

$$
X^{\lambda} \subseteq Y^{\lambda} \text { if and only if } X^{\lambda}(\hat{v}) \subseteq Y^{\lambda}(\hat{v}) \text { for all } \hat{v} \in \hat{V}
$$

Given $X^{\lambda}={ }_{\lambda} X$ and $Y^{\lambda}={ }_{\lambda} Y$, then clearly $X^{\lambda} \subseteq Y^{\lambda} \Longleftrightarrow X \subseteq Y$ and $X^{\lambda} \cup Y^{\lambda}=_{\lambda} X \cup Y$.

### 6.1.4 Algorithms

Using the recursive algorithm as a basis we can solve a VPG in numerous ways. First of all we can solve the projections, i.e. solve the VPG independently. Alternatively we can solve it collectively using a set-wise representation or a function-wise representation. For the function-wise representation we are working with functions mapping vertices and edges to sets of configurations. These sets of configurations can either be represented explicitly or symbolically. The following diagram shows the different algorithms:

The independent approach uses the original algorithm repeatedly; once for every projection. The collective set-wise approach also uses the original algorithm, applied to a unified parity game. The function-wise representation requires modifications to the algorithm, as we try to attract multiple configurations at the same time. As we will discuss later, this modified algorithm relies heavily on set operations over sets of configurations.

## Symbolically representing sets of configurations

For VPGs originating from an FTS, the configuration sets guarding the edges either admit all configurations or originate from boolean functions over the features. These boolean functions will most likely be relatively simple and are therefore specifically appropriate to represent as BDDs.

Set operations $\cap, \cup, \backslash$ over two explicit sets can be performed in $O(m)$ where $m$ is the maximum size of the sets. This is better than the time complexity of a set operation using BDDs, which is $O\left(m^{2}\right)$ (as explained in preliminary section 3.4.1. However if the BDDs are small then the set size can still be large but the set operations are performed very quickly. This is a trade-off between worst-case time complexity and actual running time; using a symbolic representation might yield better results if the sets are structured in such a way that the BDDs are small, however if the sets are not structured in a way that the BDDs are small then the running time is worse than with an explicit representation.

We hypothesize that since the collective function-wise symbolic recursive algorithm relies heavily on set operations over sets of configurations this algorithm will perform well when solving VPGs originating from FTSs.

## A note on symbolically solving games

The function-wise algorithm has two variants: an explicit and a symbolic variant. In the explicit variant both the game graph and the sets of configurations are represented explicitly. In the
symbolic variant the sets of configurations are represented symbolically, however the graph is still represented explicitly, so the algorithm is partially symbolic and partially explicit. Alternatively an algorithm could completely work symbolically by representing both the graph and the sets of configurations symbolically.

Solving parity games symbolically has been studied in [33. The obstacle is that representing graphs with a large number of nodes can make the corresponding BDDs very complex if no underlying structure is known for the graph. In such a case performance decreases rapidly. For model verification problems a game graph can conceivably be represented as a BDD by using the structure of the original model to build the BDD. However this is not trivial as argued in 33 . As to not repeat work done in [33] we only consider algorithms where we represent the graph explicitly.

### 6.1.5 Recursive algorithm using a function-wise representation

The recursive algorithm can be modified to work with the function-wise representation of vertices and edges. The algorithm behaves the same as the original; operations are modified to work with the different representation. Pseudo code for the modified algorithm is presented in Algorithm 3. Note that for this pseudo code no distinction is needed between explicit and symbolic representations of sets of configurations.

```
Algorithm 3 RecursiveUPG(unified parity game \(G=(\)
\(V^{\lambda}: \hat{V} \rightarrow 2^{\mathfrak{C}}\),
\(\hat{V}_{0} \subseteq \hat{V}\),
\(\hat{V}_{1} \subseteq \hat{V}\),
\(E^{\lambda}: \hat{E} \rightarrow 2^{\mathfrak{C}}\),
\(\hat{\Omega}: \hat{V} \rightarrow \mathbb{N})\) )
    if \(V^{\lambda}=\lambda^{\emptyset}\) then
        return \(\left(\lambda^{\emptyset},\left(\lambda^{\emptyset}\right)\right.\)
    end if
    \(h \leftarrow \max \left\{\hat{\Omega}(\hat{v}) \mid V^{\lambda}(\hat{v}) \neq \emptyset\right\}\)
    \(\alpha \leftarrow 0\) if \(h\) is even and 1 otherwise
    \(U^{\lambda} \leftarrow \lambda^{\emptyset}, U^{\lambda}(\hat{v}) \leftarrow V^{\lambda}(\hat{v})\) for all \(\hat{v}\) with \(\hat{\Omega}(\hat{v})=h\)
    \(A^{\lambda} \leftarrow \alpha-F \operatorname{Attr}\left(G, U^{\lambda}\right)\)
    \(\left(W_{0}^{\lambda^{\prime}}, W_{1}^{\lambda^{\prime}}\right) \leftarrow\) RecursiveUPG \(\left(G \backslash A^{\lambda}\right)\)
    if \(W_{\bar{\alpha}^{\prime}}=\lambda^{\emptyset}\) then
        \(W_{\alpha}^{\lambda} \leftarrow A^{\lambda} \cup W_{\alpha}^{\lambda^{\prime}}\)
        \(W_{\bar{\alpha}}^{\lambda} \leftarrow \lambda^{\emptyset}\)
    else
        \(B^{\lambda} \leftarrow \bar{\alpha}-F \operatorname{Attr}\left(G, W_{\bar{\alpha}}^{\lambda^{\prime}}\right)\)
        \(\left(W_{0}^{\lambda^{\prime \prime}}, W_{1}^{\lambda^{\prime \prime}}\right) \leftarrow\) RecursiveUPG \(\left(G \backslash B^{\lambda}\right)\)
        \(W_{\alpha}^{\lambda} \leftarrow W_{\alpha}^{\lambda^{\prime \prime}}\)
        \(W_{\bar{\alpha}}^{\lambda} \leftarrow W_{\bar{\alpha}}^{\lambda^{\prime \prime}} \cup B^{\lambda}\)
    end if
    return \(\left(W_{0}^{\lambda}, W_{1}^{\lambda}\right)\)
```

We introduce a modified attractor definition to work with the function-wise representation.

Definition 6.3. Given unified parity game $G=\left(V^{\lambda}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda}, \hat{\Omega}\right)$, represented function-wise, and a function $U^{\lambda} \subseteq V^{\lambda}$, with $U^{\lambda} \neq \lambda^{\emptyset}$, we inductively define $\alpha-F A t t r\left(G^{\lambda}, U^{\lambda}\right)$ such that

$$
U_{0}^{\lambda}(\hat{v})=U^{\lambda}(\hat{v})
$$

For $i \geq 0$ :

$$
U_{i+1}^{\lambda}(\hat{v})=U_{i}^{\lambda}(\hat{v}) \cup \begin{cases}V^{\lambda}(\hat{v}) \cap \bigcup_{\hat{v}^{\prime}}\left(E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \cap U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right) & \text { if } \hat{v} \in \hat{V}_{\alpha} \\ V^{\lambda}(\hat{v}) \cap \bigcap_{\hat{v}^{\prime}}\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \cup U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right) & \text { if } \hat{v} \in \hat{V}_{\bar{\alpha}}\end{cases}
$$

Finally:

$$
\alpha-F \operatorname{Attr}\left(G^{\lambda}, U^{\lambda}\right)(\hat{v})=\bigcup_{i \geq 0} U_{i}^{\lambda}(\hat{v})
$$

This attractor definition relies heavily on performing set operations on sets of configurations. We will show later that this definition is equal to the original attractor set definition (Definition 3.16.

We also introduce a modified subgame definition to work with the function-wise representation.
Definition 6.4. For unified parity game $G=\left(V^{\lambda}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda}, \hat{\Omega}\right)$, represented function-wise, and function $X^{\lambda} \subseteq V^{\lambda}$ we define the subgame $G \backslash X^{\lambda}=\left(V^{\lambda^{\prime}}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda^{\prime}}, \hat{\Omega}\right)$ such that:

- $V^{\lambda^{\prime}}(\hat{v})=V^{\lambda}(\hat{v}) \backslash X^{\lambda}(\hat{v})$
- $E^{\lambda^{\prime}}\left(\hat{v}, \hat{v}^{\prime}\right)=E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \cap V^{\lambda^{\prime}}(\hat{v}) \cap V^{\lambda^{\prime}}\left(\hat{v}^{\prime}\right)$

Note that we can omit the modification to the partition ( $V_{0}$ and $V_{1}$ ) because, as we have seen, we can use the partitioning from the VPG in the representation of unified parity games. As we will show later, this definition is equal to the original subgame definition (Definition 3.17).
Example 6.3. Consider unified parity game $G=\left(V^{\lambda}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda}, \hat{\Omega}\right)$, originating from a $V P G$ with configurations $\mathfrak{C}=\left\{c_{1}, c_{2}, c_{3}\right\}$, represented function-wise in Figure 6.2. We annotated every edge $(v, w)$ with the set $E^{\lambda}(v, w)$. All the origin vertices are depicted and for every origin vertex $\hat{v}$ we annotate the square or diamond with a label $\hat{v} \mid C$ where $C=V^{\lambda}(\hat{v})$. We calculate the function-wise attractor set for player 0 from origin vertex $\hat{v}_{2}$ with all configuration, we have

$$
U_{0}^{\lambda}=U^{\lambda}=\left\{\hat{v}_{1} \mapsto \emptyset, \hat{v}_{2} \mapsto \mathfrak{C}, \hat{v}_{3} \mapsto \emptyset, \hat{v}_{4} \mapsto \emptyset, \hat{v}_{5} \mapsto \emptyset, \hat{v}_{6} \mapsto \emptyset, \hat{v}_{7} \mapsto \emptyset\right\}
$$

After the first iteration we find

$$
U_{1}^{\lambda}=\left\{\hat{v}_{1} \mapsto \mathfrak{C}, \hat{v}_{2} \mapsto \mathfrak{C}, \hat{v}_{3} \mapsto \mathfrak{C}, \hat{v}_{4} \mapsto \emptyset, \hat{v}_{5} \mapsto\left\{c_{2}\right\}, \hat{v}_{6} \mapsto \emptyset, \hat{v}_{7} \mapsto \emptyset\right\}
$$

Note that $\hat{v}_{5}$ can be attracted for configuration $\left\{c_{2}\right\}$ because $\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}_{5}, \hat{v}_{7}\right)=\left\{c_{2}\right\}, U_{0}^{\lambda}\left(\hat{v}_{3}\right)=\mathfrak{C}$ and for any other origin vertex $\hat{v}$ we have $\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}_{5}, \hat{v}\right)=\mathfrak{C}$.

In the next iteration we find

$$
U_{2}^{\lambda}=\left\{\hat{v}_{1} \mapsto \mathfrak{C}, \hat{v}_{2} \mapsto \mathfrak{C}, \hat{v}_{3} \mapsto \mathfrak{C}, \hat{v}_{4} \mapsto\left\{c_{1}, c_{2}\right\}, \hat{v}_{5} \mapsto\left\{c_{2}\right\}, \hat{v}_{6} \mapsto\left\{c_{3}\right\}, \hat{v}_{7} \mapsto \emptyset\right\}
$$

Next iterations result in the same function, so $0-F A t t r\left(G, U^{\lambda}\right)=U_{2}^{\lambda}$. We create subgame $G \backslash U_{2}^{\lambda}$ depicted in Figure 6.3.

Figure 6.2: Unified parity game originating from a VPG with configurations $\mathfrak{C}=\left\{c_{1}, c_{2}, c_{3}\right\}$

In the next two lemma's we show that the function-wise attractor and subgame operators give results that are equal to the original attractor and subgame operators.

Lemma 6.1. Given:

- unified parity game $G=\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$,
- set $U \subseteq V$, and
- function $U^{\lambda}$ such that $U={ }_{\lambda} U^{\lambda}$
it holds that the function-wise attractor $\alpha-F A t t r\left(G, U^{\lambda}\right)$ is equivalent to the set-wise attractor $\alpha-\operatorname{Attr}(G, U)$ for any $\alpha \in\{0,1\}$.

Proof. Let $V$ and $E$ be the set-wise representation of the vertices and edges for game $G$. Let $V^{\lambda}$ and $E^{\lambda}$ be the function-wise representation of the vertices and edges for game $G$.

The following properties hold by definition:

$$
\begin{aligned}
(c, \hat{v}) \in V & \Longleftrightarrow c \in V^{\lambda}(\hat{v}) \\
(c, \hat{v}) \in U & \Longleftrightarrow c \in U^{\lambda}(\hat{v}) \\
\left((c, \hat{v}),\left(c, \hat{v}^{\prime}\right)\right) \in E & \Longleftrightarrow c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)
\end{aligned}
$$

Since the attractors are inductively defined and $U_{0}={ }_{\lambda} U_{0}^{\lambda}$ (because $U={ }_{\lambda} U^{\lambda}$ ) we have to prove that for some $i \geq 0$, with $U_{i}={ }_{\lambda} U_{i}^{\lambda}$, we have $U_{i+1}={ }_{\lambda} U_{i+1}^{\lambda}$, which holds iff:

$$
(c, \hat{v}) \in U_{i+1} \Longleftrightarrow c \in U_{i+1}^{\lambda}(\hat{v})
$$

Let $(c, \hat{v}) \in V$ (and therefore $c \in V^{\lambda}(\hat{v})$ ), we consider 4 cases.

Figure 6.3: Unified parity game $G \backslash U_{2}^{\lambda}$

- Case: $\hat{v} \in \hat{V}_{\alpha}$ and $(c, \hat{v}) \in U_{i+1}$ :

To prove: $c \in U_{i+1}^{\lambda}(\hat{v})$.
If $(c, \hat{v}) \in U_{i}$ then $c \in U_{i}^{\lambda}(\hat{v})$ and therefore $c \in U_{i+1}^{\lambda}(\hat{v})$. If $(c, \hat{v}) \notin U_{i}$ then we have $c \notin U_{i}^{\lambda}(\hat{v})$.
Because $\hat{v} \in \hat{V}_{\alpha}$ and $c \in V^{\lambda}(\hat{v})$ we get

$$
U_{i+1}^{\lambda}=\bigcup_{\hat{v}^{\prime}}\left(E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \cap U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right)
$$

There exists an $\left(c^{\prime}, \hat{v}^{\prime}\right) \in V$ such that $\left(c^{\prime}, \hat{v}^{\prime}\right) \in U_{i}$ and $\left((c, \hat{v}),\left(c^{\prime}, \hat{v}^{\prime}\right)\right) \in E$. Because edges do not cross configurations we can conclude that $c^{\prime}=c$. Due to equivalence we have $c \in U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)$ and $c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)$. If we fill this in in the above formula we can conclude that $c \in U_{i+1}^{\lambda}(\hat{v})$.

- Case: $\hat{v} \in \hat{V}_{\alpha}$ and $(c, \hat{v}) \notin U_{i+1}$ :

To prove: $c \notin U_{i+1}^{\lambda}(\hat{v})$.
First we observe that since $(c, \hat{v}) \notin U_{i+1}$ we get $(c, \hat{v}) \notin U_{i}$ and therefore $c \notin U_{i}^{\lambda}(\hat{v})$.
Because $\hat{v} \in \hat{V}_{\alpha}$ and $c \in V^{\lambda}(\hat{v})$ we get

$$
U_{i+1}^{\lambda}=\bigcup_{\hat{v}^{\prime}}\left(E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \cap U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right)
$$

Assume $c \in U_{i+1}^{\lambda}(\hat{v})$. There must exist a $\hat{v}^{\prime}$ such that $c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)$ and $c \in U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)$. Due to equivalence we have a vertex $\left((c, \hat{v}),\left(c, \hat{v}^{\prime}\right)\right) \in E$ and $\left(c, \hat{v}^{\prime}\right) \in U_{i}$. In which case $(c, \hat{v})$ would be attracted and would be in $U_{i+1}$ which is a contradiction.

- Case: $\hat{v} \in \hat{V}_{\bar{\alpha}}$ and $(c, \hat{v}) \in U_{i+1}$ :

To prove: $c \in U_{i+1}^{\lambda}(\hat{v})$.
If $(c, \hat{v}) \in U_{i}$ then $c \in U_{i}^{\lambda}(\hat{v})$ and therefore $c \in U_{i+1}^{\lambda}(\hat{v})$. If $(c, \hat{v}) \notin U_{i}$ then we have $c \notin U_{i}^{\lambda}(\hat{v})$.
Because $\hat{v} \in \hat{V}_{\bar{\alpha}}$ we get

$$
U_{i+1}^{\lambda}=V^{\lambda}(\hat{v}) \cap \bigcap_{\hat{v}^{\prime}}\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \cup U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right.
$$

Assume $c \notin U_{i+1}^{\lambda}(\hat{v})$. Because $c \in V^{\lambda}(\hat{v})$ there must exist an $\hat{v}^{\prime}$ such that

$$
c \notin\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \text { and } c \notin U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right.
$$

which is equal to

$$
c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \text { and } c \notin U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)
$$

By equivalence we have $\left((c, \hat{v}),\left(c, \hat{v}^{\prime}\right)\right) \in E$ and $\left(c, \hat{v}^{\prime}\right) \notin U_{i}$. Which means that $(c, \hat{v})$ will not be attracted and $(c, \hat{v}) \notin U_{i+1}$ which is a contradiction.

- Case: $\hat{v} \in \hat{V}_{\bar{\alpha}}$ and $(c, \hat{v}) \notin U_{i+1}:$

To prove: $c \notin U_{i+1}^{\lambda}(\hat{v})$.
First we observe that since $(c, \hat{v}) \notin U_{i+1}$ we get $(c, \hat{v}) \notin U_{i}$ and therefore $c \notin U_{i}^{\lambda}(\hat{v})$.
Because $\hat{v} \in \hat{V}_{\bar{\alpha}}$ we get

$$
U_{i+1}^{\lambda}=V^{\lambda}(\hat{v}) \cap \bigcap_{\hat{v}^{\prime}}\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \cup U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right.
$$

Since $(c, \hat{v})$ is not attracted there must exist a $\left(c, \hat{v}^{\prime}\right) \in V$ such that

$$
\left((c, \hat{v}),\left(c, \hat{v}^{\prime}\right)\right) \in E \text { and }\left(c, \hat{v}^{\prime}\right) \notin U_{i}
$$

By equivalence we have

$$
c \in E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \text { and } c \notin U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)
$$

Which is equal to

$$
c \notin\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \text { and } c \notin U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)
$$

From which we conclude

$$
\left.c \notin\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right)\right) \cup U_{i}^{\lambda}\left(\hat{v}^{\prime}\right)\right)\right)
$$

Therefore we have $c \notin U_{i+1}^{\lambda}(\hat{v})$.

Lemma 6.2. Given:

- unified parity game $G=\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$,
- set $U \subseteq V$ and
- function $U^{\lambda}$ such that $U={ }_{\lambda} U^{\lambda}$
it holds that the subgame $G \backslash U=\left(V^{\prime}, \hat{V}_{0}, \hat{V}_{1}, E^{\prime}, \hat{\Omega}\right)$ represented set-wise is equal to the subgame $G \backslash U^{\lambda}$ represented function-wise.

Proof. Let $V^{\lambda}$ and $E^{\lambda}$ denote the function-wise representations of $V$ and $E$ respectively. Let $G \backslash U^{\lambda}=\left(V^{\lambda^{\prime}}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda^{\prime}}, \hat{\Omega}\right)$. We know $V={ }_{\lambda} V^{\lambda}, E={ }_{\lambda} E^{\lambda}$ and $U={ }_{\lambda} U^{\lambda}$. To prove: $V^{\prime}={ }_{\lambda} V^{\lambda^{\prime}}$ and $E^{\prime}={ }_{\lambda} E^{\lambda^{\prime}}$.

1. Let $(c, \hat{v}) \in V$.

If $(c, \hat{v}) \in U$ then $c \in U^{\lambda}(\hat{v})$, also $(c, \hat{v}) \notin V^{\prime}$ (by Definition 3.17) and $c \notin V^{\lambda^{\prime}}(\hat{v}$ ) (by Definition 6.4.

If $(c, \hat{v}) \notin U$ then $c \notin U^{\lambda}(\hat{v})$, also $(c, \hat{v}) \in V^{\prime}$ (by Definition 3.17) and $c \in V^{\lambda^{\prime}}(\hat{v}$ ) (by Definition 6.4.
We conclude that $V^{\prime}={ }_{\lambda} V^{\lambda^{\prime}}$.
2. Let $((c, \hat{v}),(c, \hat{w})) \in E$.

If $(c, \hat{v}) \in U$ then $(c, \hat{v}) \notin V^{\prime}$ and $c \notin V^{\lambda^{\prime}}(\hat{v})$ (as shown above). We get $((c, \hat{v}),(c, \hat{w})) \notin$ $V^{\prime} \times V^{\prime}$ so $((c, \hat{v}),(c, \hat{w})) \notin E^{\prime}$ (by Definition 3.17). Also $c \notin E^{\lambda^{\prime}}(\hat{v}, \hat{w})$ (by Definition 6.4). If $(c, \hat{w}) \in U$ then we apply the same logic.
If neither is in $U$ then both are in $V^{\prime}$ and in $V^{\prime} \times V^{\prime}$ and therefore the $((c, \hat{v}),(c, \hat{w})) \in E^{\prime}$. Also we get $c \in V^{\lambda^{\prime}}(\hat{v})$ and $c \in V^{\lambda^{\prime}}(\hat{w})$ so we get $c \in E^{\lambda^{\prime}}(\hat{v}, \hat{w})$ (by Definition 6.4).
We conclude that $E^{\prime}={ }_{\lambda} E^{\lambda^{\prime}}$.

Next we prove the correctness of the algorithm by showing that the winning sets of the functionwise algorithm are equal to the winning sets of the set-wise algorithm.

Theorem 6.3. Given unified parity game $G=\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$ and $G^{\lambda}=\left(V^{\lambda}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda}, \hat{\Omega}\right)$ which is the functional representation of $G$. It holds that the winning sets resulting from RECURSIVEUPG $\left(G^{\lambda}\right)$ are equal to the winning sets resulting from RECURSIVEPG $(G)$.

Proof. Proof by induction on $G$.
Base: When there are no vertices then RecursiveUPG $\left(G^{\lambda}\right)$ returns ( $\lambda^{\emptyset}, \lambda^{\emptyset}$ ) and RecursivePG $(G)$ returns $(\emptyset, \emptyset)$, these two results are equal therefore the theorem holds in this case.

Step: Player $\alpha$ gets the same value in both algorithms since the highest priority is equal for both algorithms.

Let $U=\{(c, \hat{v}) \in V \mid \hat{\Omega}(\hat{v})=h\}$ (as calculated by RECURSIVEPG) and $U^{\lambda}(\hat{v})=V^{\lambda}(\hat{v})$ for all $\hat{v}$ with $\hat{\Omega}(\hat{v})=h$ (as calculated by RecursiveUPG). We will show that $U={ }_{\lambda} U^{\lambda}$.
Let $(c, \hat{v}) \in U$. Then $\hat{\Omega}(\hat{v})=h$ and therefore $U^{\lambda}(\hat{v})=V^{\lambda}(\hat{v})$. Since $U \subseteq V$ we have $(c, \hat{v}) \in V$ and because the equality between $V$ and $V^{\lambda}$ we get $c \in V^{\lambda}(\hat{v})$ and $c \in \overline{U^{\lambda}}(\hat{v})$.

Let $c \in U^{\lambda}(\hat{v})$, since $U^{\lambda}(\hat{v})$ is not empty we have $\hat{\Omega}(\hat{v})=h$, furthermore $c \in V^{\lambda}(\hat{v})$ and therefore $(c, \hat{v}) \in V$. We can conclude that $(c, \hat{v}) \in U$ and $U={ }_{\lambda} U^{\lambda}$.

For the rest of the algorithm it is sufficient to see that attractor sets are equal if the game and input set are equal (as shown in Lemma 6.1) and that the created subgames are equal (as shown in Lemma 6.2). Since the subgames are equal we can apply the theorem on it by induction and conclude that the winning sets are also equal.

Theorem 5.3 shows that solving a unified parity game solves the VPG, furthermore the algorithm RECURSIVEUPG correctly solves a unified parity game. Therefore, we can conclude that for VPG $\hat{G}$ vertex $\hat{v}$ is won by player $\alpha$ for configuration $c$ if and only if $c \in W_{\alpha}^{\lambda}(\hat{v})$ with $\left(W_{0}^{\lambda}, W_{1}^{\lambda}\right)=$ RecursiveUPG $\left(G_{\downarrow}\right)$.

## Function-wise attractor set

Next we present an algorithm to calculate the function-wise attractor, the pseudo code is presented in Algorithm 4. The algorithm considers vertices that are in the attractor set for some configuration. For every such vertex the algorithm tries to attract vertices that are connected by an incoming edge. If a vertex is attracted for some configuration then the incoming edges of that vertex will also be considered.

```
Algorithm \(4 \alpha\)-FAttractor \(\left(G, U^{\lambda}: \hat{V} \rightarrow 2^{\mathfrak{C}}\right)\)
    \(A^{\lambda} \leftarrow U^{\lambda}\)
    Queue \(Q \leftarrow\left\{\hat{v} \in \hat{V} \mid U^{\lambda}(\hat{v}) \neq \emptyset\right\}\)
    while \(Q\) is not empty do
        \(\hat{v}^{\prime} \leftarrow Q \cdot \operatorname{pop}()\)
        for every \(\hat{v}\) such that \(E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \neq \emptyset\) do
            if \(\hat{v} \in \hat{V}_{\alpha}\) then
                \(a \leftarrow V^{\lambda}(\hat{v}) \cap E^{\lambda}\left(\hat{v}, \hat{v}^{\prime}\right) \cap A^{\lambda}\left(\hat{v}^{\prime}\right)\)
            else
                    \(a \leftarrow V^{\lambda}(\hat{v})\)
                    for every \(\hat{v}^{\prime \prime}\) such that \(E^{\lambda}\left(\hat{v}, \hat{v}^{\prime \prime}\right) \neq \emptyset\) do
                        \(a \leftarrow a \cap\left(\left(\mathfrak{C} \backslash E^{\lambda}\left(\hat{v}, \hat{v}^{\prime \prime}\right)\right) \cup A^{\lambda}\left(\hat{v}^{\prime \prime}\right)\right)\)
            end for
            end if
            if \(a \backslash A^{\lambda}(\hat{v}) \neq \emptyset\) then
                \(A^{\lambda}(\hat{v}) \leftarrow A^{\lambda}(\hat{v}) \cup a\)
                Q.push \((\hat{v})\)
            end if
        end for
    end while
    return \(A^{\lambda}\)
```

We prove that the result calculated by $\alpha$-Fattractor is equal to the definition of $\alpha$-FAttr (Definition 6.3).

Theorem 6.4. Given unified parity game $G=\left(V^{\lambda}, \hat{V}_{0}, \hat{V}_{1}, E^{\lambda}, \hat{\Omega}\right)$, represented function-wise, and $U^{\lambda} \subseteq V^{\lambda}$, the algorithm $\alpha$-FATtractor $\left(G, U^{\lambda}\right)$ correctly calculates $\alpha$ - $F A t t r\left(G, U^{\lambda}\right)$.

Proof.

Termination. First note that the algorithm terminates. This follows from the fact that only vertices are added to $Q$ (line 16) when something is added to $A^{\lambda}$ (lines 14-15). Consider

$$
\operatorname{dec}\left(A^{\lambda}\right)=|\hat{V}| *|\mathfrak{C}|-\sum_{\hat{v}}\left|A^{\lambda}(\hat{v})\right|
$$

At every iteration either $\operatorname{dec}\left(A^{\lambda}\right)$ decreases or stays the same. In the latter case the size of $Q$ decreases. After finitely many iterations $\operatorname{dec}\left(A^{\lambda}\right)$ can not decrease any more so $Q$ decreases until $Q$ is empty and the algorithm terminates.

Soundness. To prove the soundness of the algorithm we must show that at the end of the algorithm we have for every $c \in A^{\lambda}(\hat{w})$ that $c \in \alpha$-FAttractor $\left(G, U^{\lambda}\right)(\hat{w})$. This property actually holds throughout the entire algorithm. Before the while loop (line 3 ) we have $A^{\lambda}=U^{\lambda}$ and the property holds trivially. Consider the beginning of a while loop iteration (the algorithm is on line 4) and assume that the property holds. The algorithm considers a number of vertices in the first for loop (line5), let $\hat{v}$ be such a vertex. The algorithm calculates $a \subseteq \mathfrak{C}$, which is added to $A^{\lambda}(\hat{v})$ on line 15 Note that this is the only place in the while loop where $A^{\lambda}$ is modified. The value calculated for $a$ on lines $6 \sqrt{13}$ exactly reflects the definition of $\alpha$-FAttr (Definition 6.3). Because we assumed that the property holds at the beginning of the while loop iteration we can conclude that $a \subseteq \alpha-F A \operatorname{ttr}\left(G, U^{\lambda}\right)(\hat{v})$. We conclude that the property is maintained during the while loop and that it holds at the end of the algorithm.

Completeness. Consider the values for $U_{i}^{\lambda}$ for $\alpha-\operatorname{FAttr}\left(G, U^{\lambda}\right)$ as defined in Definition 6.3 .
For attractor set $\alpha-\operatorname{FAttr}\left(G, U^{\lambda}\right)$ we fix strategy $\sigma_{\alpha}^{c}$ such that for every $i>0$ and $\hat{v} \in \hat{V}_{\alpha}$ with $c \in U_{i}^{\lambda}(\hat{v})$ and $c \notin U_{i-1}^{\lambda}(\hat{v})$ we have $\sigma_{\alpha}^{c}(\hat{v})=\hat{w}$ with $c \in U_{i-1}^{\lambda}(\hat{w})$. It follows from Definition 6.3 that this strategy exists and is valid for $c$. Furthermore, if the token is on $\hat{v}$ with $c \in$ $\left(\alpha-F a t t r\left(G, U^{\lambda}\right)(\hat{v}) \backslash U^{\lambda}(\hat{v})\right)$ then the token ends up in a vertex $\hat{w}$ with $c \in U^{\lambda}(\hat{w})$ for all paths that conform to $\sigma_{\alpha}^{c}$ and are valid for configuration $c$.
We introduce the following predicate to help with the proof of completeness. Predicate $\psi(c, \hat{v}, \hat{q})$ holds if and only if we have the following conditions:

- $\hat{q} \in Q$,
- $c \in A^{\lambda}(\hat{q})$ and
- there exists a path $\pi$ from $\hat{v}$ to $\hat{q}$ valid for $c$ and conforming to $\sigma_{\alpha}^{c}$ such that every vertex $\hat{w}$ between $\hat{v}$ and $\hat{q}$ in $\pi$ has $c \notin A^{\lambda}(\hat{w})$

We prove the following loop invariant over the while loop: For all $c \in \alpha-\operatorname{FAttr}\left(G, U^{\lambda}\right)(\hat{v})$ we have either $c \in A^{\lambda}(\hat{v})$ or $\exists_{\hat{q}}: \psi(c, \hat{v}, \hat{q})$.

When the while loop terminates $Q$ is empty so $\psi(c, \hat{v}, \hat{q})$ never holds and therefore we have $c \in A^{\lambda}(\hat{v})$ which shows completeness.

Initialization: Consider the values for $U_{i}^{\lambda}$ for $\alpha-F \operatorname{tttr}\left(G, U^{\lambda}\right)$ as defined in Definition 6.3. We show by induction on $i$ that the loop invariant holds for all $c \in \alpha-F A t t r\left(G, U^{\lambda}\right)(\hat{v})$ before the while loop starts.

Base $i=0$ : Before the while loop we get $A^{\lambda}=U^{\lambda}$. So the loop invariant holds for all $c \in U_{0}^{\lambda}(\hat{v})$, furthermore $\hat{v}$ is placed in $Q$.

Step $i>0$ : Consider $c \in U_{i}^{\lambda}(\hat{v})$. If $c \in U_{i-1}^{\lambda}(\hat{v})$ then we apply induction on $i-1$ to find that the loop invariant is satisfied.
If $c \notin U_{i-1}^{\lambda}$ then we distinguish two cases:

* If $\hat{v} \in \hat{V}_{\alpha}$ then we choose $\hat{w}=\sigma_{\alpha}^{c}(\hat{v})$. By the way we constructed $\sigma_{\alpha}^{c}$ we find $c \in U_{i-1}^{\lambda}(\hat{w})$. We apply induction on $i-1$ to find that either $c \in A^{\lambda}(\hat{w})$ or $\psi(c, \hat{w}, \hat{q})$ with path $\pi$. In the former case we also find $\hat{w} \in Q$ and the path $\hat{v} \hat{w}$ satisfies $\psi(c, \hat{v}, \hat{w})$. In the latter case we construct path $\hat{v} \pi$, which satisfies $\psi(c, \hat{v}, \hat{q})$. In both cases the loop invariant is satisfied.
* If $\hat{v} \in \hat{V}_{\bar{\alpha}}$ then we pick $\hat{w}$ such that $c \in E^{\lambda}(\hat{v}, \hat{w})$. Using Definition 6.3 we find that $c \in U_{i-1}^{\lambda}(\hat{w})$. We apply induction on $i-1$ to find that either $c \in A^{\lambda}(\hat{w})$ or $\psi(c, \hat{w}, \hat{q})$ with path $\pi$. In the former case we also find $\hat{w} \in Q$ and the path $\hat{v} \hat{w}$ satisfies $\psi(c, \hat{v}, \hat{w})$. In the latter case we construct path $\hat{v} \pi$, which satisfies $\psi(c, \hat{v}, \hat{q})$. In both cases the loop invariant is satisfied.

Maintenance: Assume the invariant holds at the beginning of the while loop iteration (line 4), we prove that the invariant also holds at the end of the while loop iteration (line 18).

Consider $c \in \alpha-\operatorname{FAttr}\left(G, U^{\lambda}\right)(\hat{v})$. If $c \in A^{\lambda}(\hat{v})$ by the end of the iteration then the loop invariant is maintained. Assume $c \notin A^{\lambda}(\hat{v})$ by the end of the iteration.
We find $\psi(c, \hat{v}, \hat{q})$ with path $\pi$. If $\hat{q}$ is not popped during this iteration then we can only get $\neg \exists_{\hat{q}^{\prime}}: \psi\left(c, \hat{v}, \hat{q}^{\prime}\right)$ if we find a vertex $\hat{w}$ between $\hat{v}$ and $\hat{q}$ in $\pi$ such that $c \in A^{\lambda}(\hat{w})$. Let $\hat{w}$ be the vertex closest to $\hat{v}$ in $\pi$ such that $c \in A^{\lambda}(\hat{w})$. By the beginning of the iteration we had $c \notin A^{\lambda}(\hat{w})$. So $c$ is added to $A^{\lambda}(\hat{w})$ during this iteration on line 15. In this case we find $\hat{w} \in Q$ because line 16 and $\psi(c, \hat{v}, \hat{w})$. So if $\hat{q}$ is not popped during the iteration the loop invariant holds. Assume $\hat{q}$ is popped during the iteration.
If by the beginning of the iteration we had $\psi(c, \hat{v}, \hat{q})$ and $\psi\left(c, \hat{v}, \hat{q}^{\prime}\right)$ with path $\pi^{\prime}$ such that $\hat{q} \neq \hat{q}^{\prime}$ then by the end of the iteration we either have $\psi\left(c, \hat{v}, \hat{q}^{\prime}\right)$ or $\psi(c, \hat{v}, \hat{w})$ where $\hat{w}$ is a vertex between $\hat{v}$ and $\hat{q}^{\prime}$ in $\pi^{\prime}$. In either case the loop invariants holds. Assume that by the beginning of the iteration there is a single $\hat{q}$ for which $\psi(c, \hat{v}, \hat{q})$.
Consider path $\pi$ from $\hat{v}$ to $\hat{q}$ valid for $c$ and conforming to $\sigma_{\alpha}^{c}$. If by the end of the iteration there is a vertex $\hat{w}$ between $\hat{v}$ and $\hat{q}$ such that $c \in A^{\lambda}(\hat{w})$ then we have $\psi(c, \hat{v}, \hat{w})$ and the loop invariant holds. Assume for any path from $\hat{v}$ to $\hat{q}$ valid for $c$ and conforming to $\sigma_{\alpha}^{c}$ that there is no $\hat{w}$ between $\hat{v}$ and $\hat{q}$ such that $c \in A^{\lambda}(\hat{w})$ by the end of the iteration.
Let $\pi$ be the path satisfying $\psi(c, \hat{v}, \hat{q})$ by the beginning of the iteration. Let $\pi=\ldots \hat{x} \hat{q}$ (note that it is possible that $\hat{x}=\hat{v})$. If $\hat{x} \in \hat{V}_{\alpha}$ then we find $c \in A^{\lambda}(\hat{x})$ by the end of the iteration which is a contradiction. We find $\hat{x} \in \hat{V}_{\bar{\alpha}}$.
If we get $\neg \exists_{\hat{q}^{\prime}}: \psi\left(c, \hat{x}, \hat{q}^{\prime}\right)$ by the end of the iteration then player $\bar{\alpha}$ must be able to move the token from $\hat{x}$ to a vertex $\hat{w}$ such that $\neg \exists_{\hat{q}^{\prime}}: \psi\left(c, \hat{w}, \hat{q}^{\prime}\right)$.
We have shown that the only way the loop invariant does not hold for the pair $(c, \hat{v})$ is when there exists an $\hat{x}$ owned by player $\bar{\alpha}$ such that the token can go from $\hat{x}$ to $\hat{q}$ for configuration $c$ but also from $\hat{x}$ to some $\hat{v}^{\prime}$ for which the loop invariant also not holds. Similarly to $\hat{v}$ we find that the invariant does not hold for $\hat{v}^{\prime}$ when there exists a $\hat{x}^{\prime}$ owned by player $\bar{\alpha}$ such that the token can go from $\hat{x}^{\prime}$ to $\hat{q}$ for configuration $c$ but also from $\hat{x}^{\prime}$ to some $\hat{v}^{\prime \prime}$ for which the loop invariant also not holds. For $\hat{v}^{\prime \prime}$ we find the same property.
This induces a set of vertices $\hat{X}$ such that every $\hat{x} \in \hat{X}$ is owned by player $\bar{\alpha}$ and there is a path from $\hat{x}$ to $\hat{x}^{\prime} \in \hat{X}$ valid for $c$ and conforming to $\sigma_{\alpha}^{c}$. We also find that for no $\hat{x} \in \hat{X}$ do we have $c \in U^{\lambda}(\hat{x})$ and finally that for all $\hat{x} \in \hat{X}$ we have $c \in \alpha-F A t t r\left(G, U^{\lambda}\right)(\hat{x})$. From this we
conclude that player $\bar{\alpha}$ has a strategy to keep the play in $\hat{X}$, this contradicts the properties of an attractor set. Therefore we find that the loop invariant holds for pair $(c, \hat{v})$ by the end of the iteration.

### 6.1.6 Running time

We consider the running time for solving VPG $\hat{G}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}, \hat{\Omega}, \mathfrak{C}, \theta\right)$ independently and collectively using the different types of representations. We use $n$ to denote the number of vertices, $e$ the number of edges, $d$ the number of distinct priorities and $c$ the number of configurations.

The original algorithm runs in $O\left(e * n^{d}\right)$ [17, if we run $c$ parity games independently we get $O\left(c * e * n^{d}\right)$. We can also apply the original algorithm to a unified parity game (represented set-wise) for a collective approach, in this case we get a parity game with $c * n$ vertices and $c * e$ edges, which gives a time complexity of $O\left(c * e *(c * n)^{d}\right)$. However, as we show next, this upper bound can be improved by using the property that a unified parity game consists of $c$ disconnected graphs.

We have introduced three types of collective algorithms: set-wise, function-wise with explicit configuration sets and function-wise with symbolic configuration sets. In all three algorithms the running time of the attractor set dominates the other operations performed, so we need three things: analyse the running time of the base cases, analyse the running time of the attractor set and analyse the recursion.

## Base cases

In the base cases the algorithm needs to check if there are no more vertices in the game. For the set-wise variant this is done in $O(1)$. For the function wise algorithms this is done in $O(n)$ since we have to check $V(\hat{v})=\emptyset$ for every $\hat{v}$. Note that in a symbolic representation using BDDs we can check if a set is empty in $O(1)$ because the decision diagram contains a single node when representing an empty set.

## Attractor sets

For the set-wise collective approach we can use the attractor calculation from the original algorithm which has a time complexity of $O(e)$ 42. So for a unified parity game having $c * e$ edges we have $O(c * e)$.

The function-wise variants use a different attractor algorithm. First we consider the variant where sets of configurations are represented explicitly.

Consider Algorithm 4 A vertex will be added to the queue when this vertex is attracted for some configuration, this can only happen $c * n$ times, once for every vertex-configuration combination.

During an iteration of the while loop, the first for loop considers all vertices with an edge to the vertex under consideration by the while loop. We note that during one iteration of the while loop the first for loop never considers a vertex twice. Because of this we can also conclude that during one iteration of the while loop the second for loop considers no edge twice. Since the
while loop runs at most $c * n$ times and in every iteration the second for loop considers at most $e$ edges, we conclude that the second for loop runs at most $c * n * e$ times.

The second for loop performs set operations on the set of configurations which can be done in $O(c)$ using an explicit representation. This gives a total time complexity for the attractor set of $O\left(n * c^{2} * e\right)$.

Symbolic set operations can be done in $O\left(c^{2}\right)$ so we get a time complexity of $O\left(n * c^{3} * e\right)$.
This gives the following time complexities

|  | Base | Attractor set |
| :---: | :---: | :---: |
| Set-wise | $O(1)$ | $O(c * e)$ |
| Function-wise explicit | $O(n)$ | $O\left(n * c^{2} * e\right)$ |
| Function-wise symbolic | $O(n)$ | $O\left(n * c^{3} * e\right)$ |

## Recursion

The three algorithms behave the same way with regards to their recursion, so we analyse the recursion for all three algorithms at the same time. Let $O_{B}$ denote the time complexity of the base case for the algorithm and let $O_{A}$ denote the time complexity of the attractor set. For all variants of the algorithm we have $O_{B} \leq O_{A}$ and $O_{A}+O_{B}=O_{A}$.

The algorithm has two recursions. The first recursion lowers the number of distinct priorities by 1. The second recursion removes at least one vertex. However the game is comprised of disjoint projections. We can use this fact in the analyses. Consider unified parity game $G$ and set $A$ as specified by the algorithm. Now consider the projection of $G$ to an arbitrary configuration $q, G_{\mid q}$. If $(G \backslash A)_{\mid q}$ contains a vertex that is won by player $\bar{\alpha}$ then this vertex is removed in the second recursion step. If there is no vertex won by player $\bar{\alpha}$ then the game is won in its entirety and the only vertices won by player $\bar{\alpha}$ are in different projections. We can conclude that for every configuration $q$ the second recursion either removes a vertex or $(G \backslash A)_{\mid q}$ is entirely won by player $\alpha$. Let $\bar{w}$ denote the maximum number of vertices that are won by player $\bar{\alpha}$ in game $(G \backslash A)_{\mid q}$. Since every projection has at most $n$ vertices the value for $\bar{w}$ can be at most $n$. Furthermore since $\bar{w}$ depends on $A$, which depends on the maximum priority, the value $\bar{w}$ gets reset when the top priority is removed in the first recursion. We can now write down the recursion of the algorithm:

$$
T(d, \bar{w}) \leq T(d-1, n)+T(d, \bar{w}-1)+O_{A}
$$

When $\bar{w}=0$ we will get $W_{\bar{\alpha}}=\emptyset$ as a result of the first recursion. In such a case there will be only 1 recursion.

$$
T(d, 0) \leq T(d-1, n)+O_{A}
$$

Finally we have the base cases. If $d=0$ then there are no vertices and we have the base time complexity.

$$
T(0, \bar{w}) \leq O_{B}
$$

If $d=1$ then all the vertices have the same priority, therefore the first subgame created is empty and entirely won by player $\alpha$. So we never go in the second recursion.

$$
T(1, \bar{w}) \leq T(0, n)+O_{A} \leq O_{B}+O_{A}=O_{A}
$$

Expanding the second recursion gives

$$
\begin{aligned}
& T(d) \leq(n+1) T(d-1)+(n+1) O_{A} \\
& T(1) \leq O_{A}
\end{aligned}
$$

We prove that $T(d) \leq(n+d)^{d} O_{A}$ by induction on $d$.
Base $d=1: T(1) \leq O_{A} \leq(n+1)^{1} O_{A}$
Step $d>1$ :

$$
\begin{aligned}
T(d) & \leq(n+1) T(d-1)+(n+1) O_{A} \\
& \leq(n+1)(n+d-1)^{d-1} O_{A}+(n+1) O_{A}
\end{aligned}
$$

Since $n+1 \leq n+d-1$ we get:

$$
\begin{aligned}
T(d) & \leq(n+d-1)(n+d-1)^{d-1} O_{A}+(n+1) O_{A} \\
& \leq\left((n+d-1)(n+d-1)^{d-1}+n+1\right) O_{A} \\
& \leq\left(n(n+d-1)^{d-1}+d(n+d-1)^{d-1}-(n+d-1)^{d-1}+n+1\right) O_{A} \\
& \leq\left(n(n+d)^{d-1}+d(n+d)^{d-1}-(n+d-1)^{d-1}+n+1\right) O_{A}
\end{aligned}
$$

Because $(n+d-1)^{d-1} \geq n+1$ we have $-(n+d-1)^{d-1}+n+1 \leq 0$, therefore:

$$
\begin{aligned}
T(d) & \leq\left(n(n+d)^{d-1}+d(n+d)^{d-1}\right) O_{A} \\
& \leq(n+d)(n+d)^{d-1} O_{A} \\
& \leq(n+d)^{d} O_{A}
\end{aligned}
$$

This gives a time complexity of $O\left(O_{A} *(n+d)^{d}\right)=O\left(O_{A} * n^{d}\right)$ because $n \geq d$. Filling in values for $O_{A}$ gives the following time complexities:

Recursive algorithm

## Running time in practice

Earlier we hypothesized that the symbolic function-wise algorithm could have the best performance of the 4 algorithms, however it has the worst time complexity. Our hypothesis is based on
the notion that VPGs most likely have a lot of commonalities and that sets of configurations in the VPG can be represented efficiently symbolically. Next we argue why the worst-case time complexity might not represent the running time in practice.

We dissect the running time of the function-wise algorithms. The running time complexities of the collective algorithms consist of two parts: the time complexity of the attractor set times $n^{d}$. The function-wise attractor set time complexity consists of three parts: the number of edges times the maximum number of vertices in the queue $(c * n)$ times the time complexity for set operations $\left(O(c)\right.$ for the explicit variant, $O\left(c^{2}\right)$ for the symbolic variant).

The number of vertices in the queue during attracting is at most $c * n$, however this number will only be large if we attract a very small number of configurations per time we evaluate an edge. As argued earlier we can most likely attract multiple configurations at the same time. This will decrease the number of vertices in the queue.
The time complexity of set operations is $O(c)$ when using an explicit representation and $O\left(c^{2}\right)$ when using a symbolic one. However, as shown in [44, we can implement BDDs to keep a table of already computed results. This allows us to get already calculated results in sublinear time. In total there are $2^{c}$ possible sets and therefore $2^{2 c}$ possible set combinations and $O\left(2^{c}\right)$ possible set operations that can be computed. However when solving a VPG originating from an FTS there will most likely be a relatively small number of different edge guards, in which case the number of unique sets considered in the algorithm will be small and we can often retrieve a set calculation from the computed table.

We can see that even though the running time of the collective symbolic algorithm is the worse, its practical running time might be good when we are able to attract multiple configurations at the same time and have a small number of different edge guards.

### 6.2 Incremental pre-solve algorithm

Next we explore a collective algorithm that tries to solve the VPG for all configurations as much as possible, then split the configurations in two sets, create subgames using those two configuration sets and recursively repeat the process. Specifically, we try to find vertices that are won by the same player for all configurations in $\mathfrak{C}$. If we find a vertex that is won by the same player for all configurations we call such a vertex pre-solved. The algorithm tries to recursively increase the set of pre-solved vertices until all vertices are either pre-solved or a single configuration remains. Pseudo code is presented in Algorithm 5. The algorithm is based around finding sets $P_{0}$ and $P_{1}$. We want to find these sets in an efficient manner such that the algorithm does not spent time finding vertices that are already pre-solved. Finally, when there is only a single configuration left we want an algorithm that solves the parity game $G_{\mid c}$ in an efficient manner by using the vertices that are pre-solved.

The subgames created are based on a set of configurations. We define the subgame operator as follows:

Definition 6.5. Given $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ and non-empty set $\mathfrak{X} \subseteq \mathfrak{C}$ we define the subgame $G \cap \mathfrak{X}=\left(V, V_{0}, V_{1}, E^{\prime}, \Omega, \mathfrak{C}^{\prime}, \theta^{\prime}\right)$ such that

- $\mathfrak{C}^{\prime}=\mathfrak{C} \cap \mathfrak{X}$,
- $\theta^{\prime}(e)=\theta(e) \cap \mathfrak{C}^{\prime}$ and

```
Algorithm 5 IncPreSolve \(\left(V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right), P_{0}, P_{1}\right)\)
    if \(|\mathfrak{C}|=1\) then
        Let \(\{c\}=\mathfrak{C}\)
        \(\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow\) solve \(G_{\mid c}\) using \(P_{0}\) and \(P_{1}\)
        return \(\left(\mathfrak{C} \times W_{0}^{\prime}, \mathfrak{C} \times W_{1}^{\prime}\right)\)
    end if
    \(P_{0}^{\prime} \leftarrow\) find vertices won by player 0 for all configurations in \(\mathfrak{C}\)
    \(P_{1}^{\prime} \leftarrow\) find vertices won by player 1 for all configurations in \(\mathfrak{C}\)
    if \(P_{0}^{\prime} \cup P_{1}^{\prime}=V\) then
        return \(\left(\mathfrak{C} \times P_{0}^{\prime}, \mathfrak{C} \times P_{1}^{\prime}\right)\)
    end if
    \(\mathfrak{C}^{a}, \mathfrak{C}^{b} \leftarrow\) partition \(\mathfrak{C}\) in non-empty parts
    \(\left(W_{0}^{a}, W_{1}^{a}\right) \leftarrow \operatorname{IncPreSolve}\left(G \cap \mathfrak{C}^{a}, P_{0}^{\prime}, P_{1}^{\prime}\right)\)
    \(\left(W_{0}^{b}, W_{1}^{b}\right) \leftarrow \operatorname{IncPreSolve}\left(G \cap \mathfrak{C}^{b}, P_{0}^{\prime}, P_{1}^{\prime}\right)\)
    \(W_{0} \leftarrow W_{0}^{a} \cup W_{0}^{b}\)
    \(W_{1} \leftarrow W_{1}^{a} \cup W_{1}^{b}\)
    return \(\left(W_{0}, W_{1}\right)\)
```

- $E^{\prime}=\left\{e \in E \mid \theta^{\prime}(e) \neq \emptyset\right\}$.

VPGs we consider are total, meaning that for every configuration and every vertex there is an outgoing edge from that vertex admitting that configuration. In subgames the set of configurations is restricted and only edge guards and edges are removed for configurations that fall outside the restricted set, therefore we still have totality. Furthermore it is trivial to see that every projection $G_{\mid c}$ is equal to $(G \cap \mathfrak{X})_{\mid c}$ for any $c \in \mathfrak{C} \cap \mathfrak{X}$.

Finally a subsubgame of two configuration sets is the same as the subgame of the intersection of these configuration sets, i.e. $(G \cap \mathfrak{X}) \cap \mathfrak{X}^{\prime}=G \cap\left(\mathfrak{X} \cap \mathfrak{X}^{\prime}\right)=G \cap \mathfrak{X} \cap \mathfrak{X}^{\prime}$.

### 6.2.1 Finding $P_{0}$ and $P_{1}$

We can find $P_{0}$ and $P_{1}$ using pessimistic parity games; a pessimistic parity game is a parity game created from a VPG for a player $\alpha \in\{0,1\}$ such that the parity game allows all edges that player $\bar{\alpha}$ might take but only allows edges for $\alpha$ when that edge admits all the configurations in $\mathfrak{C}$.

Definition 6.6. Given $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$, we define pessimistic parity game $G_{\triangleright \alpha}$ for player $\alpha \in\{0,1\}$, such that

$$
G_{\triangleright \alpha}=\left(V, V_{0}, V_{1}, E^{\prime}, \Omega\right)
$$

with

$$
E^{\prime}=\left\{(v, w) \in E \mid v \in V_{\bar{\alpha}} \vee \theta(v, w)=\mathfrak{C}\right\}
$$

Note that pessimistic parity games are not necessarily total. A parity game that is not total might result in a finite path, in which case the player that cannot make a move loses the path.

When solving a pessimistic parity game $G_{\triangleright \alpha}$ we get winning sets $\left(W_{0}, W_{1}\right)$. Every vertex in $W_{\alpha}$ is winning for player $\alpha$ in $G$ played for any configuration, as shown in the following theorem.

Theorem 6.5. Given:

- $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$,
- configuration $c \in \mathfrak{C}$,
- winning sets $\left(W_{0}^{c}, W_{1}^{c}\right)$ for game $G$,
- player $\alpha \in\{0,1\}$ and
- pessimistic parity game $G_{\triangleright \alpha}$ with winning sets $\left(P_{0}, P_{1}\right)$
we have $P_{\alpha} \subseteq W_{\alpha}^{c}$.

Proof. Player $\alpha$ has a strategy in game $G_{\triangleright \alpha}$ such that vertices in $P_{\alpha}$ are won. We show that this strategy can also be applied to game $G_{\mid c}$ to win the same or more vertices.

First we observe that any edge that is taken by player $\alpha$ in game $G_{\triangleright \alpha}$ can also be taken in game $G_{\mid c}$ so player $\alpha$ can play the same strategy in game $G_{\mid c}$.
For player $\bar{\alpha}$ there are possibly edges that can be taken in $G_{\triangleright \alpha}$ but cannot be taken in $G_{\mid c}$. In such a case player $\bar{\alpha}$ 's choices are limited in game $G_{\mid c}$ compared to $G_{\triangleright \alpha}$ so if player $\bar{\alpha}$ cannot win a vertex in $G_{\triangleright \alpha}$ then he/she cannot win that vertex in $G_{\mid c}$.

We can conclude that applying the strategy from game $G_{\triangleright \alpha}$ in game $G_{\mid c}$ for player $\alpha$ wins the same or more vertices. Note that this strategy might be incomplete for game $G_{\mid c}$, it could be the case that a vertex owned by player $\alpha$ in game $G_{\triangleright \alpha}$ has no successor while the same vertex has successors in $G_{\mid c}$. In such a case the vertex is never in $P_{\alpha}$ so it is not relevant to the theorem who would win this vertex in $G_{\mid c}$.

Example 6.4. Figure 6.4 shows an example VPG with corresponding pessimistic parity games. After solving the pessimistic parity games we find $P_{0}=\left\{v_{2}\right\}$ and $P_{1}=\left\{v_{0}\right\}$.

(a) VPG $G$ consisting of 2 configurations

(b) Pessimistic parity game $G_{\triangleright 0}$ with winning sets $\left(P_{0},-\right)$

(c) Pessimistic parity game $G_{\triangleright 1}$ with winning sets (,$- P_{1}$ )

Figure 6.4: A VPG with its corresponding pessimistic parity games

## Pessimistic subgames

Vertices in winning set $P_{\alpha}$ for $G_{\triangleright \alpha}$ are also winning for player $\alpha$ in pessimistic subgames of $G$, as shown in the following lemma.

Lemma 6.6. Given:

- $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$,
- $P_{0}$ being the winning set of pessimistic parity game $G_{\triangleright 0}$ for player 0 ,
- $P_{1}$ being the winning set of pessimistic parity game $G_{\triangleright 1}$ for player 1,
- non-empty set $\mathfrak{X} \subseteq \mathfrak{C}$,
- player $\alpha \in\{0,1\}$ and
- winning sets $\left(Q_{0}, Q_{1}\right)$ for pessimistic parity game $(G \cap \mathfrak{X})_{\triangleright \alpha}$
we have

$$
\begin{aligned}
& P_{0} \subseteq Q_{0} \\
& P_{1} \subseteq Q_{1}
\end{aligned}
$$

Proof. Let edge $(v, w)$ be an edge in game $G_{\triangleright \alpha}$ with $v \in V_{\alpha}$. Edge $(v, w)$ admits all configuration in $\mathfrak{C}$ so it also admits all configuration in $\mathfrak{C} \cap \mathfrak{X}$, therefore we can conclude that edge $(v, w)$ is also an edge of game $(G \cap \mathfrak{X})_{\triangleright \alpha}$.

Let edge $(v, w)$ be an edge in game $(G \cap \mathfrak{X})_{\triangleright \alpha}$ with $v \in V_{\bar{\alpha}}$. The edge admits some configuration in $\mathfrak{C} \cap \mathfrak{X}$, this configuration is also in $\mathfrak{C}$ so we can conclude that edge $(v, w)$ is also an edge of game $G_{\triangleright \alpha}$.
We have concluded that game $(G \cap \mathfrak{X})_{\triangleright \alpha}$ has the same or more edges for player $\alpha$ as game $G_{\triangleright \alpha}$ has and the same or fewer edges for player $\bar{\alpha}$. Therefore we can conclude that any vertex won by player $\alpha$ in $G_{\triangleright \alpha}$ is also won by $\alpha$ in game $(G \cap \mathfrak{X})_{\triangleright \alpha}$, i.e. $P_{\alpha} \subseteq Q_{\alpha}$.

Let $v \in P_{\bar{\alpha}}$, using Theorem6.5 we find that $v$ is winning for player $\bar{\alpha}$ in $G_{\mid c}$ for any $c \in \mathfrak{C}$. Because projections of subgames are the same as projections of the original game we can conclude that $v$ is winning for player $\bar{\alpha}$ in $(G \cap \mathfrak{X})_{\mid c}$ for any $c \in \mathfrak{C} \cap \mathfrak{X}$. Assume $v \notin Q_{\bar{\alpha}}$. Then $v \in Q_{\alpha}$ and using Theorem 6.5 we find that $v$ is winning for player $\alpha$ in $(G \cap \mathfrak{X})_{\mid c}$ for any $c \in \mathfrak{C} \cap \mathfrak{X}$. This is a contradiction so we can conclude $v \in Q_{\bar{\alpha}}$ and therefore $P_{\bar{\alpha}} \subseteq Q_{\bar{\alpha}}$.

### 6.2.2 Algorithm

In order to find $P_{0}$ and $P_{1}$ we need to solve pessimistic parity games. Specifically we want a parity game algorithm that uses the vertices that are already pre-solved to efficiently solve the pessimistic parity games. Note that when there is a single configuration left we also need a parity game algorithm that uses the vertices that are already pre-solved. In Algorithm 6 we present the IncPreSolve algorithm using pessimistic parity games. The algorithm uses a Solve algorithm for solving parity games using the pre-solved vertices. First we show the correctness of the IncPreSolve algorithm while assuming the correctness of the Solve algorithm. Later we explore an appropriate Solve algorithm.

```
Algorithm \(6 \operatorname{IncPreSolve}\left(G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right), P_{0}, P_{1}\right)\)
    if \(|\mathfrak{C}|=1\) then
        Let \(\{c\}=\mathfrak{C}\)
        \(\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow \operatorname{Solve}\left(G_{\mid c}, P_{0}, P_{1}\right)\)
        return \(\left(\mathfrak{C} \times W_{0}^{\prime}, \mathfrak{C} \times W_{1}^{\prime}\right)\)
    end if
    \(\left(P_{0}^{\prime},-\right) \leftarrow \operatorname{SoLvE}\left(G_{\triangleright 0}, P_{0}, P_{1}\right)\)
    \(\left(-, P_{1}^{\prime}\right) \leftarrow \operatorname{Solve}\left(G_{\triangleright 1}, P_{0}, P_{1}\right)\)
    if \(P_{0}^{\prime} \cup P_{1}^{\prime}=V\) then
        return \(\left(\mathfrak{C} \times P_{0}^{\prime}, \mathfrak{C} \times P_{1}^{\prime}\right)\)
    end if
    \(\mathfrak{C}^{a}, \mathfrak{C}^{b} \leftarrow\) partition \(\mathfrak{C}\) in non-empty parts
    \(\left(W_{0}^{a}, W_{1}^{a}\right) \leftarrow \operatorname{IncPreSolve}\left(G \cap \mathfrak{C}^{a}, P_{0}^{\prime}, P_{1}^{\prime}\right)\)
    \(\left(W_{0}^{b}, W_{1}^{b}\right) \leftarrow \operatorname{IncPreSolve}\left(G \cap \mathfrak{C}^{b}, P_{0}^{\prime}, P_{1}^{\prime}\right)\)
    \(W_{0} \leftarrow W_{0}^{a} \cup W_{0}^{b}\)
    \(W_{1} \leftarrow W_{1}^{a} \cup W_{1}^{b}\)
    return \(\left(W_{0}, W_{1}\right)\)
```

A Solve algorithm is correct when it correctly solves a parity game using sets $P_{0}$ and $P_{1}$, as long as $P_{0}$ and $P_{1}$ are in fact vertices that are won by player 0 and 1 respectively. We assume that the Solve algorithm is correct and prove that the values for $P_{0}$ and $P_{1}$ are always correct in IncPreSolve.

Lemma 6.7. Given VPG $\hat{G}$ and assuming the correctness of Solve. For every $\operatorname{Solve}\left(G, P_{0}, P_{1}\right)$ that is invoked during $\operatorname{IncPreSolve}(\hat{G}, \emptyset, \emptyset)$ we have winning sets $\left(W_{0}, W_{1}\right)$ for game $G$ for which the following holds:

$$
\begin{aligned}
& P_{0} \subseteq W_{0} \\
& P_{1} \subseteq W_{1}
\end{aligned}
$$

Proof. When $P_{0}=\emptyset$ and $P_{1}=\emptyset$ the theorem holds trivially. So we start the analyses after the first recursion.

After the first recursion the game is $\hat{G} \cap \mathfrak{X}$ with $\mathfrak{X}$ being either $\mathfrak{C}^{a}$ or $\mathfrak{C}^{b}$. The set $P_{0}$ is the winning set for player 0 for game $\hat{G}_{\triangleright 0}$ and the set $P_{1}$ is the winning set for player 1 for game $\hat{G}_{\triangleright 1}$. In the next recursion the game is $\hat{G} \cap \mathfrak{X} \cap \mathfrak{X}^{\prime}$ with $P_{0}$ being the winning set for player 0 in game $(\hat{G} \cap \mathfrak{X})_{\triangleright 0}$ and $P_{1}$ being the winning set for player 1 in game $(\hat{G} \cap \mathfrak{X})_{\triangleright 1}$. In general, after the $k$ th recursion, with $k>0$, the game is of the form $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right) \cap \mathfrak{X}^{k}$. Furthermore $P_{0}$ is the winning set for player 0 for game $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right)_{\triangleright 0}$ and $P_{1}$ is the winning set for player 1 for game $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right)_{\triangleright 1}$.

Next we inspect the three places where Solve is invoked:

1. Consider the case where there is only one configuration in $\mathfrak{C}$ (line 1-5). Because $P_{0}$ is the winning set for player 0 for game $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right)_{\triangleright 0}$ the vertices in $P_{0}$ are won by player 0 in game $G_{\mid c}$ for all $c \in \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}$ (using Theorem 6.5). This includes the one element in $\mathfrak{C}$. So we can conclude $P_{0} \subseteq W_{0}$ where $W_{0}$ is the winning set for player 0 in game $G_{\mid c}$ with $\{c\}=\mathfrak{C}$.
Similarly for player 1 we can conclude $P_{1} \subseteq W_{1}$ and the lemma holds in this case.
2. On line 6 the game $G_{\triangleright 0}$ is solved with $P_{0}$ and $P_{1}$. Because $G=\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1} \cap \mathfrak{X}^{k}$ and $P_{0}$ is the winning set for player 0 for game $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right)_{\triangleright 0}$ and $P_{1}$ is the winning set for player 1 for game $\left(\hat{G} \cap \mathfrak{X}^{1} \cap \cdots \cap \mathfrak{X}^{k-1}\right)_{\triangleright 1}$ we can apply Lemma 6.6 to conclude that the lemma holds in this case.
3. On line 7 we apply the same reasoning and lemma to conclude that the lemma holds in this case.

Next we prove the correctness of the algorithm, assuming the correctness of the Solve algorithm.
Theorem 6.8. Given $V P G G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ with winning sets $\left(W_{0}^{c}, W_{1}^{c}\right)$ and $\left(W_{0}, W_{1}\right)=$ $\operatorname{IncPreSolve}(G, \emptyset, \emptyset)$. For every configuration $c \in \mathfrak{C}$ it holds that:

$$
\begin{aligned}
& (c, v) \in W_{0} \Longleftrightarrow v \in W_{0}^{c} \\
& (c, v) \in W_{1} \Longleftrightarrow v \in W_{1}^{c}
\end{aligned}
$$

Proof. We assumed that $\operatorname{Solve}\left(G^{\prime}, P_{0}, P_{1}\right)$ correctly solves $G^{\prime}$ as long as vertices in $P_{0}$ and $P_{1}$ are won by player 0 and 1 respectively. Lemma 6.7 shows that this is always the case when invoking IncPreSolve $(G, \emptyset, \emptyset)$. We therefore find that $\operatorname{Solve}\left(G^{\prime}, P_{0}, P_{1}\right)$ always correctly solves $G^{\prime}$ during the algorithm.

We prove the theorem by applying induction on $\mathfrak{C}$.
Base $|\mathfrak{C}|=1$ : When there is only one configuration, being $c$, then the algorithm solves game $G_{\mid c}$. The product of the winning sets and $\{c\}$ is returned, so the theorem holds.
Step: Consider $P_{0}^{\prime}$ and $P_{1}^{\prime}$ as calculated in the algorithm (line 6-7). By Theorem 6.5 all vertices in $P_{0}^{\prime}$ are won by player 0 in game $G_{\mid c}$ for any $c \in \mathfrak{C}$, similarly for $P_{1}^{\prime}$ and player 1 .
If $P_{0}^{\prime} \cup P_{1}^{\prime}=V$ then the algorithm returns $\left(\mathfrak{C} \times P_{0}^{\prime}, \mathfrak{C} \times P_{1}^{\prime}\right)$. In which case the theorem holds because there are no configuration vertex combinations that are not in either winning set and Theorem 6.5 proves the correctness.

If $P_{0}^{\prime} \cup P_{1}^{\prime} \neq V$ then we have winning sets $\left(W_{0}^{a}, W_{1}^{a}\right)$ for which the theorem holds (by induction) for game $G \cap \mathfrak{C}^{a}$ and ( $W_{0}^{b}, W_{1}^{b}$ ) for which the theorem holds (by induction) for game $G \cap \mathfrak{C}^{b}$. The algorithm returns $\left(W_{0}^{a} \cup W_{0}^{b}, W_{1}^{a} \cup W_{1}^{b}\right)$. Since $\mathfrak{C}^{a} \cup \mathfrak{C}^{b}=\mathfrak{C}$ and $\mathfrak{C}^{a} \cap \mathfrak{C}^{b}=\emptyset$ all vertex configuration combinations are in the winning sets and the correctness follows from induction.

### 6.2.3 A parity game algorithm using $P_{0}$ and $P_{1}$

We can modify the fixed-point iteration algorithm to solve parity games using pre-solved vertices. Recall that the fixed-point iteration algorithm calculates an alternating fixed-point formula to find the winning set for player 0 . When iterating fixed-point formula $\mu X . f(X)$ we choose some initial value for $X$ and keep iterating $f(X)$ until we find $X=f(X)$. The original fixed-point iteration algorithm chooses $\emptyset$ as the initial value. In this section we show that given $P_{0}$ and $P_{1}$ we can use the fixed-point iteration algorithm, but instead of choosing initial value $\emptyset$ we choose initial value $P_{0}$. This will most likely decrease the number of iterations needed before we find $X=f(X)$. Moreover we show that we can ignore vertices in $P_{0}$ in parts of the calculation
because we already know these vertices are winning. Similarly, we find that we can choose initial value $V \backslash P_{1}$ instead of $V$ (where $V$ is the set of vertices) when iterating a greatest fixed-point formula and ignore vertices in $P_{1}$.

We choose to use the fixed-point parity game algorithm because the modified version using presolved vertices is very similar to the original version. When experimenting with the incremental pre-solve algorithm we can compare its performance with the performance of independently solving the projections using the fixed-point iteration algorithm to get a good idea of how well the incremental pre-solve idea performs.

First recall the fixed-point formula to calculate $W_{0}$ :

$$
S(G)=\nu Z_{d-1} \cdot \mu Z_{d-2} \ldots \ldots \nu Z_{0} \cdot F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right)
$$

with

$$
\begin{aligned}
F_{0}\left(G=\left(V, V_{0}, V_{1}, E, \Omega\right), Z_{d-1}, \ldots, Z_{0}\right) & =\left\{v \in V_{0} \mid \exists_{w \in V}(v, w) \in E \wedge w \in Z_{\Omega(w)}\right\} \\
& \cup\left\{v \in V_{1} \mid \forall_{w \in V}(v, w) \in E \Longrightarrow w \in Z_{\Omega(w)}\right\}
\end{aligned}
$$

Also recall that we can calculate a least fixed-point as follows:

$$
\mu X . f(X)=\bigcup_{i \geq 0} X^{i}
$$

where $X^{i}=f\left(X^{i-1}\right)$ for $i>0$ and $X^{0} \subseteq \mu X . f(X)$. So picking the smallest value possible for $X_{0}$ will always correctly calculate $\mu X . f(X)$. Similarly we can calculate fixed-point a greatest fixed-point as follows:

$$
\nu X \cdot f(X)=\bigcap_{i \geq 0} X^{i}
$$

where $X^{i}=f\left(X^{i-1}\right)$ for $i>0$ and $X^{0} \supseteq \nu X . f(X)$. So picking the largest value possible for $X_{0}$ will always correctly calculate $\nu X . f(X)$.

Let $G$ be a parity game and let sets $P_{0}$ and $P_{1}$ be such that vertices in $P_{0}$ are won by player 0 and vertices in $P_{1}$ are won by player 1 . We can fixed-point iterate $S(G)$ to calculate $W_{0}$. We know that $W_{0}$ is bounded by $P_{0}$ and $P_{1}$, specifically we have

$$
P_{0} \subseteq W_{0} \subseteq V \backslash P_{1}
$$

We will prove that formula

$$
S^{P}(G)=\nu Z_{d-1} \cdot \mu Z_{d-2} \ldots \nu Z_{0} \cdot\left(F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right) \cap\left(V \backslash P_{1}\right) \cup P_{0}\right)
$$

also solves $W_{0}$ for $G$. Note that the formula $F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right) \cap\left(V \backslash P_{1}\right) \cup P_{0}$ is still monotonic, as shown in Lemma 6.9.
Lemma 6.9. Given lattice $\left\langle 2^{D}, \subseteq\right\rangle$, monotonic function $f: 2^{D} \rightarrow 2^{D}$ and $A \subseteq D$. The functions $f^{\cup}(x)=f(x) \cup A$ and $f^{\cap}(x)=f(x) \cap A$ are also monotonic.

Proof. Let $x, y \subseteq D$ and $x \subseteq y$ then $f(x) \subseteq f(y)$.
Let $e \in f(x) \cup A$. If $e \in f(x)$ then $e \in f(y)$ and $e \in f(y) \cup A$. If $e \in A$ then $e \in f(y) \cup A$. We find $f^{\cup}(x) \subseteq f^{\cup}(y)$.

Let $e \in f(x) \cap A$. We have $e \in f(x)$ and $e \in A$. Therefore $e \in f(y)$ and $e \in f(y) \cap A$. We find $f^{\cap}(x) \subseteq f^{\cap}(y)$.

## Fixed-point iteration index

We introduce the notion of fixed-point iteration indices to help with the proof of $S^{P}$.
Consider the following alternating fixed-point formula:

$$
\nu X_{m-1} \cdot \mu X_{m-2} \ldots \nu X_{0} \cdot f\left(X_{m-1}, \ldots, X_{0}\right)
$$

Using fixed-point iteration to solve this formula results in a number of intermediate values for the iteration variables $X_{m-1}, \ldots X_{0}$. We define an iteration index that, intuitively, indicates where in the iteration process we are. For an alternating fixed-point formula with $m$ fixed-point variables we define an iteration index $\zeta \subseteq \mathbb{N}^{m}$.

When applying iteration to formula $\nu X_{j} . f(X)$ we start with some value for $X_{j}^{0}$ and calculate $X_{j}^{i+1}=f\left(X_{j}^{i}\right)$. So we get a list of values for $X_{j}$, however when we have alternating fixed-point formulas we might iterate $X_{j}$ multiple times but get different lists of values because the values for $X_{m-1}, \ldots, X_{j-1}$ have changed. We use the iteration index to distinguish between these different lists.

Iteration index $\zeta=\left(k_{m-1}, \ldots, k_{0}\right)$ indicates where in the iteration process we are. We start at $\zeta=(0,0, \ldots, 0)$ and first iterate $X_{0}$. When we calculate $X_{0}^{1}$ we are at iteration index $\zeta=$ $(0,0, \ldots, 1)$, when we calculate $X_{0}^{2}$ we are at iteration index $\zeta=(0,0, \ldots, 2)$ and so on. In general when we calculate a value for $X_{j}^{i}$ then $k_{j}=i$ in $\zeta$. This induces the lexicographical order

$$
\begin{gathered}
(0, \ldots, 0,0,0) \\
(0, \ldots, 0,0,1) \\
(0, \ldots, 0,0,2) \\
\vdots \\
(0, \ldots, 0,1,0) \\
(0, \ldots, 0,1,1) \\
(0, \ldots, 0,1,2)
\end{gathered}
$$

We define $\left\{k_{m-1}, \ldots, k_{0}\right\}-1=\left\{k_{m-1}, \ldots, k_{0}-1\right\}$ and $\left\{k_{m-1}, \ldots, k_{0}\right\}+1=\left\{k_{m-1}, \ldots, k_{0}+1\right\}$ for convenience of notation.
We write $X_{j}^{\zeta}$ to indicate the value of variable $X_{j}$ at moment $\zeta$ in the iteration process. Variable $X_{j}$ does not change values when a variable $X_{l}$ with $j>l$ changes values; we have for indexes $\zeta=\left(k_{m-1}, \ldots, k_{j}, k_{j-1}, \ldots, k_{0}\right)$ and $\zeta^{\prime}=\left(k_{m-1}, \ldots, k_{j}, k_{j-1}^{\prime}, \ldots, k_{0}^{\prime}\right)$ that $X_{j}^{\zeta}=X_{j}^{\zeta^{\prime}}$.

We use the fixed-point iteration definition to define the values for $X_{j}^{\zeta}$. Let $\zeta=\left(k_{m-1}, \ldots, k_{0}\right)$, we have:

$$
X_{0}^{\zeta+1}=f\left(X_{m-1}^{\zeta}, \ldots, X_{0}^{\zeta}\right)
$$

and for any even $0<j<m$

$$
X_{j}^{\left(\ldots, k_{j}+1, \ldots\right)}=\mu X_{j-1} \cdots=\bigcup_{i \geq 0} X^{\left(\ldots, k_{j}, i, \ldots\right)}
$$

and for any odd $0<j<m$

$$
X_{j}^{\left(\ldots, k_{j}+1, \ldots\right)}=\nu X_{j-1} \cdots=\bigcap_{i \geq 0} X^{\left(\ldots, k_{j}, i, \ldots\right)}
$$

$\Gamma$-games We define $\Gamma$, which transforms a parity game, to help with the proof. The $\Gamma$ operator removes the pre-solved vertices from a game and modifies it such that the winners of the remaining vertices are preserved.

Definition 6.7. Given parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ with winning set $W_{0}$ such that $P_{0} \subseteq$ $W_{0} \subseteq V \backslash P_{1}$. We define $\Gamma\left(G, P_{0}, P_{1}\right)=\left(V^{\prime}, V_{0}^{\prime}, V_{1}^{\prime}, E^{\prime}, \Omega^{\prime}\right)$ such that

$$
\begin{aligned}
& V^{\prime}=\left(V \backslash P_{0} \backslash P_{1}\right) \cup\left\{s_{0}, s_{1}\right\} \\
& V_{0}^{\prime}=\left(V_{0} \cap V^{\prime}\right) \cup\left\{s_{1}\right\} \\
& V_{1}^{\prime}=\left(V_{1} \cap V^{\prime}\right) \cup\left\{s_{0}\right\} \\
& E^{\prime}=\left(E \cap\left(V^{\prime} \times V^{\prime}\right)\right) \cup\left\{\left(v, s_{\alpha}\right) \mid(v, w) \in E \wedge w \in P_{\alpha}\right\} \\
& \Omega^{\prime}(v)= \begin{cases}0 & \text { if } v \in\left\{s_{0}, s_{1}\right\} \\
\Omega(v) & \text { otherwise }\end{cases}
\end{aligned}
$$

Parity game $\Gamma\left(G, P_{0}, P_{1}\right)$ contains vertices $s_{0}$ and $s_{1}$ such that they have no outgoing edges and $s_{\alpha}$ is owned by player $s_{\bar{\alpha}}$. Clearly if the token ends in $s_{\alpha}$ then player $\alpha$ wins. Vertices that had edges to a vertex in $P_{\alpha}$ now have an edge to $s_{\alpha}$.
Note that because $s_{0}$ and $s_{1}$ do not have successors, their priorities do not matter for winning sets of $G^{\prime}$. Also note that this parity game is not total, as shown in 43 the formula $S(G)$ also solves non-total games.

Next we show that vertices in $V \backslash P_{0} \backslash P_{1}$ have the same winner in games $G$ and $G^{\prime}$.
Lemma 6.10. Given parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ with winning set $W_{0}$ such that $P_{0} \subseteq W_{0} \subseteq$ $V \backslash P_{1}$ and parity game $G^{\prime}=\Gamma\left(G, P_{0}, P_{1}\right)$ with winning set $Q_{0}$ we have $W_{0} \backslash P_{0} \backslash P_{1}=Q_{0} \backslash\left\{s_{0}, s_{1}\right\}$.

Proof. Let vertex $v \in V \backslash P_{0} \backslash P_{1}$. Assume $v$ is won by player $\alpha$ in $G$ using strategy $\sigma_{\alpha}: V_{\alpha} \rightarrow V$. We construct a strategy $\sigma_{\alpha}^{\prime}: V_{\alpha}^{\prime} \rightarrow V^{\prime}$ for game $G^{\prime}$ as follows:

$$
\sigma_{\alpha}^{\prime}(w)= \begin{cases}s_{\beta} & \text { if } \sigma_{\alpha}(w) \in P_{\beta} \text { for some } \beta \in\{0,1\} \\ \sigma_{\alpha}(w) & \text { otherwise }\end{cases}
$$

This strategy maps the vertices to the same successors except when a vertex is mapped to a vertex in $P_{\beta}$, in which case $\sigma_{\alpha}^{\prime}$ maps the vertex to $s_{\beta}$.

Let $\pi^{\prime}$ be a valid path in $G^{\prime}$, starting from $v$ and conforming to $\sigma_{\alpha}^{\prime}$. Since vertices $s_{0}$ and $s_{1}$ do not have any successors we distinguish three cases for $\pi^{\prime}$ :

- Assume $\pi^{\prime}$ ends in $s_{\bar{\alpha}}$. Let $\pi^{\prime}=\left(x_{0} \ldots x_{m} s_{\bar{\alpha}}\right)$ with $v=x_{0}$. Because $s_{0}$ and $s_{1}$ do not have successors no $x_{i}$ is $s_{0}$ or $s_{1}$; we find $x_{i} \in V \backslash P_{0} \backslash P_{1}$. For every $x_{i} x_{i+1}$ we have $\left(x_{i}, x_{i+1}\right) \in E^{\prime}$, any such edge is also in $E$ because the edges between vertices in $V \backslash P_{0} \backslash P_{1}$ were left intact when creating $G^{\prime}$. Finally we find that $\left(x_{m}, y\right) \in E$ with $y \in P_{\bar{\alpha}}$. There must exist a valid path $\pi=\left(x_{0} \ldots x_{m} y \ldots\right)$ in game $G$ conforming to $\sigma_{\alpha}$ because $\sigma_{\alpha}^{\prime}$ and $\sigma_{\alpha}$ map to the same vertices for all $x_{0} \ldots x_{m-1}$ and $x_{m}$ maps to a vertex in $P_{\bar{\alpha}}$. Player $\bar{\alpha}$ has a winning strategy from $y$ so we conclude that $\pi$ is won by $\bar{\alpha}$ in game $G$. Because $\pi$ exists and conforms to $\sigma_{\alpha}$ we find that $\sigma_{\alpha}$ is not winning for $\alpha$ from $v$ in $G$. This is a contradiction so we conclude that $\pi^{\prime}$ never ends in $s_{\bar{\alpha}}$.
- Assume $\pi^{\prime}$ ends in $s_{\alpha}$. In this case player $\alpha$ wins the path.
- Assume $\pi^{\prime}$ never visits $s_{\alpha}$ or $s_{\bar{\alpha}}$. Assume the path is won by player $\bar{\alpha}$, as we argued above we find that this path is also valid in game $G$, conforms to $\sigma_{\alpha}$ and is winning for $\bar{\alpha}$. Therefore $\sigma_{\alpha}$ is not winning for player $\alpha$ from $v$ in game $G$, this is a contradiction so we conclude that player $\alpha$ wins the path $\pi^{\prime}$.

We find that $\pi^{\prime}$ is always won by player $\alpha$ in game $G^{\prime}$. We conclude that any vertex $v \in V \backslash P_{0} \backslash P_{1}$ won by player $\alpha$ in game $G$ is also won by player $\alpha$ in $G^{\prime}$.

Let $v \in V^{\prime} \backslash\left\{s_{0}, s_{1}\right\}$. Let $v$ be won by player $\alpha$ in game $G^{\prime}$. Assume that $v$ is not won by $\alpha$ in game $G$ then $v$ is won by $\bar{\alpha}$ in game $G$. Clearly $v \in V \backslash P_{0} \backslash P_{1}$ so we conclude that $v$ is won by player $\bar{\alpha}$ in game $G^{\prime}$. This is a contradiction so $v$ is won by player $\alpha$ in game $G$.

Proof Using the $\Gamma$ operator and the iteration indices we can now prove the correctness of $S^{P}$.
Theorem 6.11. Given parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$ with winning set $W_{0}$ such that $P_{0} \subseteq$ $W_{0} \subseteq V \backslash P_{1}$. The formula

$$
S^{P}(G)=\nu Z_{d-1} \cdot \mu Z_{d-2} \ldots \nu Z_{0} \cdot\left(F_{0}\left(G, Z_{d-1}, \ldots, Z_{0}\right) \cap\left(V \backslash P_{1}\right) \cup P_{0}\right)
$$

correctly solves $W_{0}$ for $G$.
Proof. Let $G^{\prime}=\left(V^{\prime}, V_{0}^{\prime}, V_{1}^{\prime}, E^{\prime}, \Omega^{\prime}\right)=\Gamma\left(G, P_{0}, P_{1}\right)$. We consider $S\left(G^{\prime}\right)$, which calculates the winning set for player 0 for game $G^{\prime}$. Formula $F_{0}\left(G^{\prime}, Z_{d-1}, \ldots, Z_{0}\right)$ will always include $s_{0}$ and never include $s_{1}$, regardless of the values for $Z_{d-1} \ldots Z_{0}$. Clearly any $\nu Z_{i} \ldots$ or $\mu Z_{i} \ldots$ contains $s_{0}$ and does not contain $s_{1}$. As shown in [13] we can start the iteration of least fixed-point formula $\mu X . f(X)$ at any value $X^{0} \subseteq \mu X . f(X)$. Similarly, we can start the iteration of greatest fixed-point formula $\nu X . f(X)$ at any value $X^{0} \supseteq \nu X . f(X)$. So we can calculate $S\left(G^{\prime}\right)$ using fixedpoint iteration, starting least fixed-point variables at $\left\{s_{0}\right\}$ and greatest fixed-point variables at $V^{\prime} \backslash\left\{s_{1}\right\}$.

We can also calculate $S^{P}(G)$ using fixed-point iteration starting at $P_{0}$ and $V \backslash P_{1}$ because clearly any $\nu Z_{i} \ldots$ or $\mu Z_{i} \ldots$ contains all vertices from $P_{0}$ and none from $P_{1}$.
We prove the theorem by going through the iteration process of $S^{P}(G)$ and $S\left(G^{\prime}\right)$ simultaneously. We write $Z_{i}$ to denote variables in $S\left(G^{\prime}\right)$ and $Y_{i}$ to denote variables in $S^{P}(G)$. We will show that for any iteration index $\zeta$ any iteration variable $Z_{i}^{\zeta}$ is equal to $Y_{i}^{\zeta}$ for vertices $V \backslash P_{0} \backslash P_{1}$, that is $Y_{i}^{\zeta} \backslash P_{0} \backslash P_{1}=Z_{i}^{\zeta} \backslash\left\{s_{0}, s_{1}\right\}$. We only prove that this is the case when we start iteration of $S^{P}(G)$ at $P_{0}$ and $V \backslash P_{1}$ and start iteration of $S\left(G^{\prime}\right)$ at $\left\{s_{0}\right\}$ and $V^{\prime} \backslash\left\{s_{1}\right\}$. As argued above, starting at these values correctly calculates $S^{P}(G)$ and $S\left(G^{\prime}\right)$.

Trivially, for any $\zeta$ and $i \in[0, d-1]$ we have $P_{0} \subseteq Y_{i}^{\zeta} \subseteq V \backslash P_{1}$ and $\left\{s_{0}\right\} \subseteq Z_{i}^{\zeta} \subseteq V \backslash\left\{s_{1}\right\}$.
We define operator $\simeq: V \times V^{\prime} \rightarrow \mathbb{B}$ such that for $Y \subseteq V$ and $Z \subseteq V^{\prime}$ we have $Y \simeq Z$ if and only if:

$$
Y \backslash P_{0} \backslash P_{1}=Z \backslash\left\{s_{0}, s_{1}\right\}
$$

We prove, by induction on $\zeta$, that for any $\zeta=\left(k_{d-1}, \ldots, k_{0}\right)$ we have $Y_{i}^{\zeta} \simeq Z_{i}^{\zeta}$ for every $i \in[0, d-1]$.

Base $\zeta=(0,0, \ldots, 0)$ : we have for least fixed-point variables $Z_{i}^{\zeta}$ and $Y_{i}^{\zeta}$ the values $\left\{s_{0}\right\}$ and $P_{0}$, clearly $Y_{i}^{\zeta} \simeq Z_{i}^{\zeta}$.

For greatest fixed-point variables $Z_{j}^{\zeta}$ and $Y_{j}^{\zeta}$ we have $Z_{j}^{\zeta} \backslash\left\{s_{0}, s_{1}\right\}=V \backslash P_{1} \backslash P_{0}$. So we find $Y_{j}^{\zeta} \simeq Z_{j}^{\zeta}$.

Step: Consider $\zeta=\left(k_{d-1}, \ldots, k_{0}\right)$. Let $j \in[0, d-1]$. If $k_{j}=0$ then $Z_{j}^{\zeta}=Z_{j}^{(0,0, \ldots, 0)}$ and $Y_{j}^{\zeta}=Y_{j}^{(0,0, \ldots, 0)}$, furthermore $Z_{j}^{(0,0, \ldots, 0)} \simeq Y_{j}^{(0,0, \ldots, 0)}$ so we find $Y_{j}^{\zeta} \simeq Z_{j}^{\zeta}$. If $k_{j}>0$ then we distinguish three cases for $j$ to show that $Y_{j}^{\zeta} \simeq Z_{j}^{\zeta}$ :

- Case $j=0$ : We have the following equations:

$$
Y_{0}^{\zeta}=F_{0}\left(G, Y_{d-1}^{\zeta-1}, \ldots, Y_{0}^{\zeta-1}\right) \cap\left(V \backslash P_{1}\right) \cup P_{0}
$$

and

$$
Z_{0}^{\zeta}=F_{0}\left(G^{\prime}, Z_{d-1}^{\zeta-1}, \ldots, Z_{0}^{\zeta-1}\right)
$$

By induction we find $Y_{i}^{\zeta-1} \simeq Z_{i}^{\zeta-1}$ for all $i \in[0, d-1]$.
Consider vertex $v \in V \backslash P_{0} \backslash P_{1}$. We distinguish two cases:

- Assume $v \in V_{0}$.

If $v \in Y_{0}^{\zeta}$ then $v$ must have an edge in game $G$ to $w$ such that $w \in Y_{\Omega(w)}^{\zeta-1}$. We find $w \notin P_{1}$ because vertices from $P_{1}$ are never in the iteration variable. If $w \in P_{0}$ then it follows from the way we created $G^{\prime}$ that in $G^{\prime}$ there exists an edge from $v$ to $s_{0}$ and since $s_{0}$ is always in the iteration variable we find $v \in Z_{0}^{\zeta}$. If $w \notin P_{0}$ then because $Y_{\Omega(w)}^{\zeta-1} \simeq Z_{\Omega(w)}^{\zeta-1}$ we find $w \in Z_{\Omega(w)}^{\zeta-1}$ and therefore $v \in Z_{0}^{\zeta}$.
If $v \in Z_{0}^{\zeta}$ then $v$ must have an edge in game $G^{\prime}$ to $w$ such that $w \in Z_{\Omega(w)}^{\zeta-1}$. We find $w \neq s_{1}$ because $s_{1}$ is never in the iteration variable. If $w=s_{0}$ then it follows from the way we created $G^{\prime}$ that in $G$ there exists an edge from $v$ to a vertex in $P_{0}$ and since any vertex in $P_{0}$ is always in the iteration variable we find $v \in Y_{0}^{\zeta}$. If $w \neq s_{0}$ then because $Y_{\Omega(w)}^{\zeta-1} \simeq Z_{\Omega(w)}^{\zeta-1}$ we find $w \in Y_{\Omega(w)}^{\zeta-1}$ and therefore $v \in Y_{0}^{\zeta}$.

- Assume $v \in V_{1}$.

If $v \in Y_{0}^{\zeta}$ then for any successor $w$ of $v$ in game $G$ it holds that $w \in Y_{\Omega(w)}^{\zeta-1}$. Consider successor $x$ of $v$ in game $G^{\prime}$. We distinguish three cases:

* $x=s_{0}$ : In this case $x \in Z_{\Omega(x)}^{\zeta-1}$ because $s_{0}$ is always in the iteration variables.
* $x=s_{1}$ : Because of the way $G^{\prime}$ is constructed we find vertex $v$ must have a successor $w$ in $P_{1}$ in game $G$. However we found $w \in Y_{\Omega(w)}^{\zeta-1}$. This is a contradiction because vertices in $P_{1}$ are never in the iteration variables. So this case can not happen.
* $x \notin\left\{s_{0}, s_{1}\right\}$ : We have $x \in V^{\prime} \backslash\left\{s_{0}, s_{1}\right\}$ and therefore $x$ is also a successor of $v$ in game $G$. We find $x \in Y_{\Omega(x)}^{\zeta-1}$ and because $Y_{\Omega(x)}^{\zeta-1} \simeq Z_{\Omega(x)}^{\zeta-1}$ we have $x \in Z_{\Omega(x)}^{\zeta-1}$.
We always find $x \in Z_{\Omega(x)}^{\zeta-1}$, therefore $v \in Z_{0}^{\zeta}$.
If $v \in Z_{0}^{\zeta}$ then for any successor $w$ of $v$ in game $G^{\prime}$ it holds that $w \in Z_{\Omega(w)}^{\zeta-1}$. Consider successor $x$ of $v$ in game $G$. We distinguish three cases:
* $x \in P_{0}$ : In this case $x \in Y_{\Omega(x)}^{\zeta-1}$ because vertices in $P_{0}$ are always in the iteration variables.
* $x \in P_{1}$ : Because of the way $G^{\prime}$ is constructed we find vertex $v$ must have successor $s_{1}$ in game $G^{\prime}$, however we found that for any successor $w$ of $v$ in game $G^{\prime}$ we have $w \in Z_{\Omega(w)}^{\zeta-1}$. This is a contradiction because $s_{1}$ is never in the iteration variable. So this case can not happen.
* $x \in V \backslash P_{0} \backslash P_{1}$ : We find that $x$ is also a successor of $v$ in game $G^{\prime}$. We find $x \in Z_{\Omega(w)}^{\zeta-1}$ and because $Y_{\Omega(x)}^{\zeta-1} \simeq Z_{\Omega(x)}^{\zeta}$ we have $x \in Y_{\Omega(x)}^{\zeta}$.
We always find $x \in Y_{\Omega(x)}^{\zeta-1}$, therefore $v \in Y_{0}^{\zeta}$.
- Case $j>0$ being even: We have

$$
Z_{j}^{\zeta}=\mu Z_{j-1} \cdots=\bigcup_{i \geq 0} Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}
$$

and

$$
Y_{j}^{\zeta}=\mu Y_{j-1} \cdots=\bigcup_{i \geq 0} Y_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}
$$

Let $v \in V \backslash P_{0} \backslash P_{1}$.
If $v \in Z_{j}^{\zeta}$ then there exists some $i$ such that $v \in Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}$. Since $\left\{k_{d-1}, \ldots, k_{j}-\right.$ $1, i, \ldots\}<\zeta$ we apply induction to find $Y_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}} \simeq Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}$. Because $v \in V \backslash P_{0} \backslash P_{1}$ we find $v \in Y_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}$ and therefore $v \in Y_{j}^{\zeta}$.
If $v \in Y_{j}^{\zeta}$ then we apply symmetrical reasoning to find $v \in Z_{j}^{\zeta}$.

- Case $j>0$ being odd: We have

$$
Z_{j}^{\zeta}=\nu Z_{j-1} \cdots=\bigcap_{i \geq 0} Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}
$$

and

$$
Y_{j}^{\zeta}=\nu Y_{j-1} \cdots=\bigcap_{i \geq 0} Y_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}
$$

Let $v \in V \backslash P_{0} \backslash P_{1}$.
If $v \in Z_{j}^{\zeta}$ then for all $i \geq 0$ we have $v \in Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}$. Assume $v \notin Y_{j}^{\zeta}$, there must exist an $l \geq 0$ such that $v \notin Y_{j}^{\left\{k_{d-1}, \ldots, k_{j}-1, l, \ldots\right\}}$. Since $\left\{k_{d-1}, \ldots, k_{j}-1, l, \ldots\right\}<\zeta$ we apply induction to find $Y_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, l, \ldots\right\}} \simeq Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, l, \ldots\right\}}$. Because $v \in V \backslash P_{0} \backslash P_{1}$ we find $v \notin Z_{j-1}^{\left\{k_{d-1}, \ldots, k_{j}-1, i, \ldots\right\}}$ which is a contradiction so we have $v \in Y_{j}^{\zeta}$.
If $v \in Y_{j}^{\zeta}$ then we apply symmetrical reasoning to find $v \in Z_{j}^{\zeta}$.
This proves that for any $\zeta$ we have $Y_{i}^{\zeta} \simeq Z_{i}^{\zeta}$ for every $i \in[0, d-1]$.
We have shown that when starting the iteration of $S\left(G^{\prime}\right)$ and $S^{P}(G)$ at specific values we get identical results for vertices in $V \backslash P_{0} \backslash P_{1}$. We chose these values such that they solve the formulas correctly, so we conclude that $S\left(G^{\prime}\right) \backslash\left\{s_{0}, s_{1}\right\}=S^{P}(G) \backslash P_{0} \backslash P_{1}$. Lemma 6.10 shows that $S\left(G^{\prime}\right)$
correctly solves vertices in $V \backslash P_{0} \backslash P_{1}$ for game $G$. So $S^{P}(G)$ also correctly solves vertices $V \backslash P_{0} \backslash P_{1}$ for game $G$.

Moreover, any vertex in $P_{0}$ is in $S^{P}(G)$, which is correct because $P_{0}$ vertices are winning for player 0 . Any vertex in $P_{1}$ is not in $S^{P}(G)$, which is correct because $P_{1}$ vertices are winning for player 1 . We conclude that all vertices are correctly solved by $S^{P}(G)$.

## Algorithm

We use the original fixed-point algorithm presented in 4] and modify it such that its starts in iteration at $P_{0}$ and $V \backslash P_{1}$. Moreover, we ignore vertices in $P_{0}$ or $P_{1}$ in the diamond and box calculation. Finally we always add vertices in $P_{0}$ to the results of the diamond and box operator. The correctness follow from Theorem 6.11 and 4, 43].
Note that in [4] total games are used. However, it is argued that the algorithm correctly solves the formula presented in 43]. The only property of parity games that is used in this argumentation is that parity games have a unique owner and priority. Clearly this is still the case for total parity games so the algorithm correctly solves the formula presented in 43. In 43] it is shown that the formula also correctly solves non-total parity games.

This algorithm can be used as a Solve algorithm in IncPreSolve since it solves parity games using $P_{0}$ and $P_{1}$.

### 6.2.4 Running time

We consider the running time for solving VPG $G=\left(V, V_{0}, V_{1}, E, \Omega, \mathfrak{C}, \theta\right)$ independently and collectively. We use $n$ to denote the number of vertices, $e$ the number of edges, $d$ the number of distinct priorities and $c$ the number of configurations.

The fixed-point iteration algorithm without $P_{0}$ and $P_{1}$ runs in $O\left(e * n^{d}\right)$ 4. We can use this algorithm to solve $G$ independently, i.e. solve all the projections of $G$. This gives a time complexity of $O\left(c * e * n^{d}\right)$.

Next, consider the IncPreSolve algorithm for a collective approach, observe that in the worst case we have to split the set of configurations all the way down to individual configurations. We can consider the recursion as a tree where the leafs are individual configurations and at every internal node the set of configurations is split in two. In the worst case there are $c$ leaves so there are at most $c-1$ internal nodes. At every internal node the algorithm solves two games and at every leaf the algorithm solves 1 game, so we get $O(c+2 c-2)=O(c)$ parity games that are being solved by IncPreSolve. In the worst case the values for $P_{0}$ and $P_{1}$ are empty. In this case the FPITE algorithm behaves the same as the original algorithm and has a time complexity of $O\left(e * n^{d}\right)$. This gives an overall time complexity of $O\left(c * e * n^{d}\right)$, which is equal to an independent solving approach.

## Running time in practice

The incremental pre-solve algorithm will, most likely, need to solve more (pessimistic) parity games than an independent approach would need to solve. However, the algorithm keeps trying to increase the number of pre-solved vertices which might speed up the solving of these games. This would cause the algorithm to solve the (pessimistic) increasingly quickly. Therefore, we hypothesize that, even though more games are solved, the increment pre-solve algorithm performs better than an independent approach.

## 7. Locally solving (variability) parity games

As discussed in the preliminaries, parity games can be solved either globally or locally. Similar to parity games we can solve VPGs either globally or locally. When locally solving a VPG for vertex $\hat{v}_{0}$ we determine for every configuration the winner of vertex $\hat{v}_{0}$. When globally solving a VPG we determine this for every vertex in the VPG.

When solving a VPG globally we might encounter significant differences in parts of the game or intermediate results between configurations that we perhaps do not encounter when solving it locally because we can terminate earlier. Therefore we hypothesize that the increase in performance between globally-collectively solving VPGs and locally-collectively solving VPGs is greater than the increase in performance between globally-independently solving VPGs and locally-independently solving VPGs.

The algorithms we have seen thus far are global algorithms. In this section we introduce local variants for the parity game algorithms we have seen: Zielonka's recursive algorithm and fixedpoint iteration algorithm. Furthermore, we introduce local variants for the novel VPG algorithms: the recursive algorithm for VPGs and the incremental pre-solve algorithm.

### 7.1 Locally solving parity games

The two parity game algorithms introduced in the preliminaries (Zielonka's recursive algorithm and the fixed-point iteration algorithm) can be turned into local variants. These local variants can be used to solve VPGs locally and independently.

### 7.1.1 Local recursive algorithm for parity games

The recursive algorithm has two recursion steps. The first recursion step gives two winning sets which are used to find set $B$ such that all the vertices in $B$ won are by a particular player. The second recursion step solves the remaining part of the game. When locally solving a parity game we can sometimes avoid entering the second recursion when we already found the vertex we are interested in to be in set $B$. In this section we introduce an algorithm that utilizes this idea to create a local variant of the recursive algorithm.

First we inspect the notion of traps [45]. Traps are used in the original proof of the recursive algorithm and we will use them again to reason about a local variant of the recursive algorithm. Consider total parity game $\left(V, V_{0}, V_{1}, E, \Omega\right)$ in the next definition and two lemma's.
Definition 7.1. [45] Set $X \subseteq V$ is an $\alpha$-trap in $G$ if and only if player $\bar{\alpha}$ can play in such a way that once the token is in $X$, it will not leave $X$.
Lemma 7.1. 45] Set $V \backslash \alpha-\operatorname{Attr}(G, X)$ is an $\alpha$-trap in $G$ for any non-empty set $X \subseteq V$.
Lemma 7.2. 45] Let $X \subseteq V$ be an $\alpha$-trap in $G$. Then $\bar{\alpha}-\operatorname{Attr}(G, X)$ is also an $\alpha$-trap in $G$.
Observe that a winning set $W_{\alpha}$ of parity game $G$ is an $\bar{\alpha}$-trap in $G$. If $\bar{\alpha}$ could play to $W_{\bar{\alpha}}$ from a vertex $v \in W_{\alpha}$ then $v$ would be winning for $\bar{\alpha}$.

We show that if a vertex in the first recursion is won by player $\bar{\alpha}$, as calculated in the recursive algorithm, then this vertex is also won by player $\bar{\alpha}$ in the game itself.
Lemma 7.3. Given total parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$, player $\alpha \in\{0,1\}$ and non-empty set $X \subseteq V$ it holds that the winning set $W_{\bar{\alpha}}$ for player $\bar{\alpha}$ in $G^{\prime}=G \backslash \alpha-\operatorname{Attr}(G, X)$ is an $\alpha$-trap in $G$ and all vertices in $W_{\bar{\alpha}}$ are winning for $\bar{\alpha}$ in $G$.

Proof. Using Lemma 7.1 we find that $V^{\prime}=V \backslash \alpha-\operatorname{Attr}(G, X)$ is a an $\alpha$-trap in $G$. Set $W_{\bar{\alpha}}$ is an $\alpha$-trap in $G$ because if $\alpha$ could escape to $V \backslash V^{\prime}$ then $V^{\prime}$ would not be an $\alpha$-trap in $G$ and if $\alpha$ could escape to $V^{\prime} \backslash W_{\bar{\alpha}}$ then $W_{\bar{\alpha}}$ would not be an $\alpha$-trap in $G^{\prime}$. Moreover keeping the token in $W_{\bar{\alpha}}$ causes player $\bar{\alpha}$ to win the path because the strategy that was winning in $G^{\prime}$ can also be applied in $G$.

Let $v_{0}$ be the vertex we are trying to solve locally. We could argue that if the algorithm finds $v_{0}$ to be winning for player $\bar{\alpha}$ in the first recursion of the algorithm then we can terminate and report $v_{0}$ to be winning for $\bar{\alpha}$. Using the lemma above we find that indeed $v_{0}$ is winning for player $\bar{\alpha}$ in game $G$ when $v_{0}$ is winning for $\bar{\alpha}$ in the first recursion. However game $G$ itself might be the subgame of some game $H$. Vertex $v_{0}$ is winning for $\bar{\alpha}$ in $G$ and in the subgame created in the first recursion; however if we want to terminate early then $v_{0}$ must also be winning for $\bar{\alpha}$ in game $H$. If $v_{0}$ is not winning for $\bar{\alpha}$ in game $H$ and game $G$ is the first subgame created from game $H$ then in order to correctly solve game $H$ we need the complete winning sets of $G$. In the conjecture below we express this property. If the conjecture holds we can terminate when we find $v_{0}$ in the first recursion to be winning for player $\bar{\alpha}$. However, as is shown below, the conjecture does not hold.

Conjecture 7.4 (Disproven). For any RecursivePG $\left(G^{\prime} \backslash A\right)$, with winning sets $\left(W_{0}^{\prime}, W_{1}^{\prime}\right)$, that is invoked during RecursivePG $(G)$ it holds that any vertex $v \in W_{\bar{\alpha}}^{\prime}$ is won by player $\bar{\alpha}$ in game $G$.

Counterexample. Consider the following parity game $G$ :

All vertices are won by player 0 ( $v_{1}$ plays to $v_{3}, v_{3}$ must play to $v_{2}$ and $v_{2}$ must play to itself; we always get an infinite path of $v_{2}$ 's).
We solve this game using RecursivePG and write down the values of relevant variables below. We use the tilde decoration to indicate values for variables in the first recursion:

```
RecursivePG( \(G\) ):
\(h=3, \alpha=1\)
\(A=\left\{v_{3}\right\}\)
    RecursivePG \((G \backslash A)\) :
    \(\tilde{h}=2, \tilde{\alpha}=0\)
    \(\tilde{A}=\left\{v_{2}\right\}\)
    \(\mid \operatorname{RecursivePG}(G \backslash A \backslash \tilde{A})\)
    \(\tilde{W}_{0}^{\prime}=\emptyset\)
    \(\tilde{W}_{1}^{\prime}=\left\{v_{1}\right\}=\tilde{W}_{\tilde{\alpha}}^{\prime}\)
    Vertex \(v_{1}\) is in \(\tilde{W}_{\tilde{\alpha}}^{\prime}\) however in \(G\) the vertex is won by player \(\tilde{\alpha}\).
    \(\tilde{B}=\left\{v_{1}\right\}\)
    \(\mid \operatorname{RecursivePG}(G \backslash A \backslash \tilde{B})\)
    \(\tilde{W}_{0}^{\prime \prime}=\left\{v_{2}\right\}, \tilde{W}_{1}^{\prime \prime}=\emptyset\)
\(W_{0}^{\prime}=W_{\bar{\alpha}}^{\prime}=\left\{v_{2}\right\}\)
```

```
\(W_{1}^{\prime}=W_{\alpha}^{\prime}=\left\{v_{1}\right\}\)
\(B=V\)
| RecursivePG \((G \backslash B)\)
\(W_{0}=W_{\bar{\alpha}}=V\)
```

This counterexample disproves the conjecture.

When $v_{0}$ is not winning for player $\bar{\alpha}$ in the first recursion then we need the complete winning sets to calculate $B$ and go in the next recursion. We extend the recursive algorithm with a variable $\Delta \subseteq\{0,1\}$. The algorithm either returns partial winning sets, containing $v_{0}$, when $v_{0}$ is won by player $\beta \in \Delta$ or the algorithm returns complete winning sets. This solves the problem, that Conjecture 7.4 does not hold, by only allowing the algorithm to terminate before the second recursion when $\bar{\alpha}$ is in $\Delta$. Pseudo code for the algorithm using $\Delta$ is provided in Algorithm 8 .

```
Algorithm 8 RecursivePGLocal(parity game \(\left.G=\left(V, V_{0}, V_{1}, E, \Omega\right), v_{0}, \Delta\right)\)
    if \(V=\emptyset\) then
        return \((\emptyset, \emptyset)\)
    end if
    \(h \leftarrow \max \{\Omega(v) \mid v \in V\}\)
    \(\alpha \leftarrow 0\) if \(h\) is even and 1 otherwise
    \(U \leftarrow\{v \in V \mid \Omega(v)=h\}\)
    \(A \leftarrow \alpha-\operatorname{Attr}(G, U)\)
    if \(\bar{\alpha} \in \Delta\) then
        \(\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow\) RecursivePGLocal \(\left(G \backslash A, v_{0},\{\bar{\alpha}\}\right)\)
    else
        \(\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow \operatorname{RecursivePGLocal}\left(G \backslash A, v_{0}, \emptyset\right)\)
    end if
    if \(W_{\bar{\alpha}}^{\prime}=\emptyset\) then
        \(W_{\alpha} \leftarrow A \cup W_{\alpha}^{\prime}\)
        \(W_{\bar{\alpha}} \leftarrow \emptyset\)
    else
        \(B \leftarrow \bar{\alpha}-\operatorname{Attr}\left(G, W_{\bar{\alpha}}^{\prime}\right)\)
        if \(\bar{\alpha} \in \Delta \wedge v_{0} \in B\) then
            \(W_{\alpha} \leftarrow \emptyset\)
            \(W_{\bar{\alpha}} \leftarrow B\)
        else
            \(\left(W_{0}^{\prime \prime}, W_{1}^{\prime \prime}\right) \leftarrow\) RecursivePGLocal \(\left(G \backslash B, v_{0}, \Delta\right)\)
            \(W_{\alpha} \leftarrow W_{\alpha}^{\prime \prime}\)
            \(W_{\bar{\alpha}} \leftarrow W_{\bar{\alpha}}^{\prime \prime} \cup B\)
        end if
    end if
    return \(\left(W_{0}, W_{1}\right)\)
```

To prove the correctness we show any vertex in the winning set $W_{\gamma}$ resulting from RECURSIVEPGLocal is indeed winning for player $\gamma$ and that either the winning sets completely partition the graph or that vertex $v_{0}$ is in winning set $W_{\beta}$ such that $\beta \in \Delta$.

The proof is in many ways similar to the proof given in 45. We repeat part of the original reasoning in the following lemma.

Lemma 7.5. Given:

- total parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$,
- non-empty set $X \subseteq V$ such that $X$ is an $\alpha$-trap in $G$ and all vertices in $X$ are winning for player $\bar{\alpha}$ in game $G$,
- subgame $G^{\prime}=G \backslash \bar{\alpha}-\operatorname{Attr}(G, X)$
it holds that the winner of any vertex in $G^{\prime}$ is also the winner of that vertex in $G$.

Proof. Let $\left(W_{0}^{\prime}, W_{1}^{\prime}\right)$ be the winning sets of game $G^{\prime}$. Using Lemma 7.2 we find that $\bar{\alpha}-\operatorname{Attr}(G, X)$ is an $\alpha$-trap in $G$. Using lemma 7.1 we find that $V^{\prime}=V \backslash \bar{\alpha}-\operatorname{Attr}(G, X)$ is an $\bar{\alpha}$-trap in $G$.

Consider winning set $W_{\alpha}^{\prime}$ for game $G^{\prime}$. Set $W_{\alpha}^{\prime}$ is an $\bar{\alpha}$-trap in $G^{\prime}$. In game $G$ we find that player $\bar{\alpha}$ can not escape $W_{\alpha}^{\prime}$ by going to $V \backslash V^{\prime}$ because $V^{\prime}$ is an $\bar{\alpha}$-trap in $G$. Furthermore player $\bar{\alpha}$ can not escape to $W_{\bar{\alpha}}^{\prime}$ because $W_{\alpha}^{\prime}$ is an $\bar{\alpha}$-trap in $G^{\prime}$. We find that $W_{\alpha}$ is an $\bar{\alpha}$-trap in $G$. Finally we know that the strategy for player $\alpha$ used in game $G^{\prime}$ is still applicable in game $G$ to win the vertices in $W_{\alpha}^{\prime}$ for game $G$.
Consider winning set $W_{\bar{\alpha}}^{\prime}$ for game $G^{\prime}$. Set $W_{\bar{\alpha}}^{\prime}$ is an $\alpha$-trap in $G^{\prime}$. In game $G$ we find that player $\alpha$ can not escape $W_{\bar{\alpha}}^{\prime}$ by going to $W_{\alpha}^{\prime}$, however he/she might escape by going to $V \backslash V^{\prime}=$ $\bar{\alpha}-\operatorname{Attr}(G, X)$. When play goes to $\bar{\alpha}-\operatorname{Attr}(G, X)$ then player $\bar{\alpha}$ can get the play into $X$ which is an $\alpha$-trap in $G$ and is winning for player $\bar{\alpha}$ in $G$. So when the token is in $W_{\bar{\alpha}}^{\prime}$ either the play stays there and $\bar{\alpha}$ uses the strategy from game $G^{\prime}$ to win or the play goes to $X$ where player $\bar{\alpha}$ can keep the play and win.

Theorem 7.6. Given total parity game $G=\left(V, V_{0}, V_{1}, E, \Omega\right)$, vertex $v_{0}$ (which is not necessarily in $V), \Delta \subseteq\{0,1\}$ and winning sets $\left(Q_{0}, Q_{1}\right)$ for game $G$. We have for sets $\left(W_{0}, W_{1}\right)=$ RecursivePGLocal $\left(G, v_{0}, \Delta\right)$ that at least one of the following statements hold:
(I) For some $\beta \in \Delta$ we have $v_{0} \in W_{\beta}, W_{0} \subseteq Q_{0}$ and $W_{1} \subseteq Q_{1}$.
(II) $W_{0}=Q_{0}$ and $W_{1}=Q_{1}$.

Proof. First note that both statements require the vertices in the winning sets to be in the correct winning sets. Statement (I) only allows winning sets to be incomplete, it does not allow vertices to be in a winning set when that vertex is not actually won by that player. Furthermore note that statement (II) simply states that the game is solved completely.

Proof by induction on $G$.
Base: When $G$ is empty then the algorithm returns ( $\emptyset, \emptyset$ ) in which case statement (II) holds trivially.

Step: The algorithm considers the highest priority in the game and assigns the parity of this priority to $\alpha$. The set $U$ contains all vertices with this priority and $A$ contains all vertices from where player $\alpha$ can force the play into $U$.

The first recursion removes vertices in $A$ from the game, since $A$ is non-empty we can apply induction to find that at least one of the two statements hold for $G \backslash A$ and winning sets ( $W_{0}^{\prime}, W_{1}^{\prime}$ ).

If $W_{\bar{\alpha}}^{\prime}=\emptyset$ (line 13) then statement (II) must be true for $G \backslash A$ because $\alpha$ is never passed into the $\Delta$ parameter for recursion $G \backslash A$ (lines 9 and 11). We find that indeed all vertices in $G \backslash A$ are won by player $\alpha$, moreover player $\alpha$ has a strategy $\sigma_{\alpha}$ for $G \backslash A$ that is winning for all vertices in $V \backslash A$. Clearly this strategy can also be applied game to $G$. Consider valid path $\pi$ in game $G$ conforming to $\sigma_{\alpha}$. When this path eventually stays in $V \backslash A$ then player $\alpha$ wins because $\sigma_{\alpha}$ is winning here. Otherwise the path visits $A$ infinitely often, in which case player $\alpha$ can force the play infinitely often into $U$ and therefore the highest priority occurring infinitely often has parity $\alpha$. So player $\alpha$ wins all vertices in $V$ and the algorithm returns winning sets accordingly; statement (II) holds.
If $W_{\bar{\alpha}}^{\prime} \neq \emptyset$ we use Lemma 7.3 and induction on $G \backslash A$ to find that all vertices in $W_{\bar{\alpha}}^{\prime}$ are also won by player $\bar{\alpha}$ in game $G$.

The algorithm continues with calculating set $B$ (line 17). If $\bar{\alpha} \in \Delta$ and $v_{0} \in B$ (line 18) then the algorithm returns all vertices in $B$ to be winning for player $\bar{\alpha}$. As argued, all vertices in $W_{\bar{\alpha}}^{\prime}$ are winning for player $\bar{\alpha}$ in game $G$. Clearly any vertex where player $\bar{\alpha}$ can force the play to $W_{\bar{\alpha}}^{\prime}$ is also winning for player $\bar{\alpha}$. So all vertices in $B$ are winning for player $\bar{\alpha}$ in $G$. Because $v_{0} \in B$ and $\bar{\alpha} \in \Delta$, statement (I) holds for game $G$.
If $\bar{\alpha} \notin \Delta$ or $v_{0} \notin B$ then statement(II) holds for game $G \backslash A$ (because $W_{\bar{\alpha}}^{\prime} \subseteq B$ ).
The algorithm goes into the second recursion (line 22). Using induction we find that any vertex $v \in W_{\beta}^{\prime \prime}$ is indeed won by player $\beta$ in game $G \backslash B$. The algorithm returns $v$ to be winning for player $\beta$ in game $G$, using Lemma 7.5 we find this to be correct. Note that we can apply Lemma 7.5 because statement (II) holds for $G \backslash A$ and using Lemma 7.3 we find that $W_{\bar{\alpha}}^{\prime}$ is an $\alpha$-trap in $G$. The algorithm also returns $B$ to be winning for $\bar{\alpha}$, which is correct because it contains vertices such that player $\bar{\alpha}$ can play to $W_{\bar{\alpha}}^{\prime}$ where player $\bar{\alpha}$ wins. If statement (II) holds for $G \backslash B$ then statement (II) also holds for $G$. If statement (I) holds for $G \backslash B$ then statement (I) also holds for $G$ because we pass $\Delta$ into the recursion unmodified.

Calling RecursivePGLocal $\left(G, v_{0},\{0,1\}\right)$ with $v_{0}$ in $G$ either solves the full game (statement (II)) or correctly puts $v_{0}$ in either winning set (statement (I)). In both cases $v_{0}$ is in the correct winning set and the game is solved locally.

The worst-case time complexity of the local variant is the same as the original algorithm: $O(e *$ $n^{d}$ ). If vertex $v_{0}$ is not winning for a player in $\Delta$ then the algorithm behaves the same as the original, so its worst-case time complexity is the same.

### 7.1.2 Local fixed-point iteration algorithm

The fixed-point iteration algorithm can be modified to locally solve a parity game for vertex $v_{0}$ by distinguishing two cases:

1. If $d-1$ is even then the outermost fixed-point variable is a greatest fixed-point variable. When at some point $v_{0} \notin Z_{d-1}$ then we know $v_{0}$ is never won by player 0 and we are done.
2. If $d-1$ is odd then the outermost fixed-point variable is a least fixed-point variable. When at some point $v_{0} \in Z_{d-1}$ then we know $v_{0}$ is won by player 0 and we are done.

If vertex $v_{0}$ is won by player 0 in the first case or won by player 1 in the second case then the algorithm never terminates early. So in the worst-case the local algorithm behaves the same as the global algorithm, therefore we have identical worst-case time complexities of $O\left(e * n^{d}\right)$.

### 7.2 Locally solving variability parity games

We consider the two collective VPG algorithms we have seen thus far and create local variants of them.

### 7.2.1 Local recursive algorithm for variability parity games

In the previous section we have seen a local variant of Zielonka's recursive algorithm for parity games that uses $\Delta \subseteq\{0,1\}$ to indicate for which player we are trying to find the specific vertex.
Consider VPG $\hat{G}$ with configuration set $\mathfrak{C}$ and origin vertex $\hat{v}_{0}$ which we are trying to solve locally. Unified parity game $\hat{G}_{\downarrow}$ contains vertices $\mathfrak{C} \times\left\{\hat{v}_{0}\right\}$. If we find the winning player for each of these vertices we have solved the VPG locally. We are going to solve a unified parity game locally, but instead of finding the winner of a single vertex we are finding the winners for a set of vertices, specifically $\mathfrak{C} \times\left\{\hat{v}_{0}\right\}$.

When we locally solve a parity game using the recursive algorithm we can sometimes avoid the second recursion because we already found the winner of $\hat{v}_{0}$. However, when locally solving a unified parity game we might find $\hat{v}_{0}$ for some configuration but not for all. When we find $\hat{v}_{0}$ to be won by player $\bar{\alpha} \in \Delta$ for configurations $C \subseteq \mathfrak{C}$ then we remove all vertices with configurations $C$ from the game, i.e. we remove vertices $C \times \hat{V}$. For the remaining vertices we do go into the second recursion. Pseudo code is presented in Algorithm 9 we introduce function LocalConfs which returns the configurations for which we have found the local solution.

The algorithm uses definitions to reason about projections of unified parity games and sets to configuration(s). Previously we introduced a simple projection definition that projects a unified parity game to a configuration (Definition 5.2). This is possible because vertices in a unified parity game consist of pairs of configurations and origin vertices. We define a similar projection for sets of vertices consisting of pairs of configurations and origin vertices.
Definition 7.2. Given set $X \subseteq(\mathfrak{C} \times \hat{V})$ we define the projection of $X$ to $c \in \mathfrak{C}$, denoted by $X_{\mid c}$, as

$$
X_{\mid c}=\{\hat{v} \mid(c, \hat{v}) \in X\}
$$

Furthermore we need to be able to reason about projections not only to a single vertex but to a group of vertices.
Definition 7.3. Given set $X \subseteq(\mathfrak{C} \times \hat{V})$ we define the projection of $X$ to $C \subseteq \mathfrak{C}$, denoted by $X_{\| C}$, as

$$
X_{\| C}=X \cap(C \times \hat{V})
$$

We prove the correctness of Algorithm 9 by showing that every projection of the unified parity game is either solved globally or locally. We first prove the following auxiliary lemma to reason about projections.
Lemma 7.7. Given unified parity game $G=\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$, configuration $c \in \mathfrak{C}$ and non-empty set $X \subseteq(\mathfrak{C} \times \hat{V})$ such that $X_{\mid c} \neq \emptyset$, it holds that $\alpha-\operatorname{Attr}(G, X)_{\mid c}=\alpha-\operatorname{Attr}\left(G_{\mid c}, X_{\mid c}\right)$.

```
Algorithm 9 RecursiveUPGLocal(parity game \(G=(\)
\(V \subseteq \mathfrak{C} \times \hat{V}\),
\(\hat{V}_{0} \subseteq \hat{V}\),
\(\hat{V}_{1} \subseteq \hat{V}\),
\(E \subseteq(\mathfrak{C} \times \hat{V}) \times(\mathfrak{C} \times \hat{V})\),
\(\hat{\Omega}: \hat{V} \rightarrow \mathbb{N})\),
\(\hat{v}_{0} \in \hat{V}\),
\(\Delta \subseteq\{0,1\})\)
```

    if \(V=\emptyset\) then
    return \((\emptyset, \emptyset)\)
    function LocalConfs $(X \subseteq V)$
if $\bar{\alpha} \in \Delta$ then
return $\left\{c \in \mathfrak{C} \mid\left(c, \hat{v}_{0}\right) \in X\right\}$
end if
$h \leftarrow \max \{\hat{\Omega}(\hat{v}) \mid(c, \hat{v}) \in V\}$
else return $\emptyset$
$\alpha \leftarrow 0$ if $h$ is even and 1 otherwise
$U \leftarrow\{(c, \hat{v}) \in V \mid \hat{\Omega}(\hat{v})=h\}$
$A \leftarrow \alpha-\operatorname{Attr}(G, U)$
end if
end function
if $\bar{\alpha} \in \Delta$ then
$\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow \operatorname{RecursiveUPGLocaL}\left(G \backslash A, \hat{v}_{0},\{\bar{\alpha}\}\right)$
else
$\left(W_{0}^{\prime}, W_{1}^{\prime}\right) \leftarrow \operatorname{RecursiveUPGLocaL}\left(G \backslash A, \hat{v}_{0}, \emptyset\right)$
end if
if $W_{\bar{\alpha}}^{\prime}=\emptyset$ then
$W_{\alpha} \leftarrow A \cup W_{\alpha}^{\prime}$
$W_{\bar{\alpha}} \leftarrow \emptyset$
else
$B \leftarrow \bar{\alpha}-\operatorname{Attr}\left(G, W_{\bar{\alpha}}^{\prime}\right)$
$C_{B} \leftarrow \operatorname{LocalConfs}(B)$
$\left(W_{0}^{\prime \prime}, W_{1}^{\prime \prime}\right) \leftarrow$ RecursiveUPGLocal $\left(G \backslash B \backslash\left(V_{| | C_{B}}\right), \hat{v}_{0}, \Delta\right)$
$W_{\alpha} \leftarrow W_{\alpha}^{\prime \prime}$
$W_{\bar{\alpha}} \leftarrow W_{\bar{\alpha}}^{\prime \prime} \cup B$
end if
return $\left(W_{0}, W_{1}\right)$

Proof. This lemma follows immediately from the fact that a unified parity game is the union of its projections. Furthermore, edges in unified parity games do not cross configurations, i.e. for any $\left((c, v),\left(c^{\prime}, v^{\prime}\right)\right) \in E$ we get $c=c^{\prime}$.

Next we prove the correctness. We prove that either the projection onto a configuration is solved globally by the algorithm or in the projection $\hat{v}_{0}$ is found to be winning for player $\beta \in \Delta$. This is very similar to the local recursive algorithm for parity games (Algorithm 8 and Theorem 7.6 ) where we proved similar properties.

Theorem 7.8. Given:

- $V P G \hat{G}=\left(\hat{V}, \hat{V}_{0}, \hat{V}_{1}, \hat{E}, \hat{\Omega}, \mathfrak{C}, \theta\right)$,
- origin vertex $\hat{v}_{0} \in \hat{V}$,
- total unified parity game $G=\left(V, \hat{V}_{0}, \hat{V}_{1}, E, \hat{\Omega}\right)$ that is a subgame of, or equal to, unified parity game $\hat{G}_{\downarrow}$,
- configuration $c \in \mathfrak{C}$,
- winning sets $\left(Q_{0}, Q_{1}\right)$ for game $G_{\mid c}$,
- a set of players $\Delta \subseteq\{0,1\}$ and
- winning sets $\left(W_{0}, W_{1}\right)=\operatorname{RecursiveUPGLocal}\left(G, \hat{v}_{0}, \Delta\right)$
at least one of the following statements hold:
(I) For some $\beta \in \Delta$ we have $\left(c, \hat{v}_{0}\right) \in W_{\beta},\left(W_{0}\right)_{\mid c} \subseteq Q_{0}$ and $\left(W_{1}\right)_{\mid c} \subseteq Q_{1}$.
(II) $\left(W_{0}\right)_{\mid c}=Q_{0}$ and $\left(W_{1}\right)_{\mid c}=Q_{1}$.

Proof. Proof by induction on $G$.
Base: If $G$ is empty then the algorithm returns ( $\emptyset, \emptyset$ ) in which case statement (II) holds trivially.
Step: When $G_{\mid c}$ is empty then $\left(W_{0}\right)_{\mid c}=\emptyset$ and $\left(W_{1}\right)_{\mid c}=\emptyset$ because the algorithm only returns vertices in the winning sets that are in $V$. In this case statement (II) holds trivially. Assume for the remainder of the proof that $G_{\mid c}$ is not empty, that is $V_{\mid c} \neq \emptyset$.
The algorithm considers the highest priority in the game and assigns the parity of this priority to $\alpha$. The set $U$ contains all vertices with this priority and $A$ contains all vertices from where player $\alpha$ can force the play into $U$.

The first recursion removes vertices in $A$ from the game. Since $A$ is non-empty we can apply induction to find that at least one of the two statements hold for $G \backslash A$ and winning sets ( $W_{0}^{\prime}, W_{1}^{\prime}$ ).
If $W_{\bar{\alpha}}^{\prime}=\emptyset$ (line 13 ) then no vertex is won by player $\bar{\alpha}$ in $G \backslash A$ and therefore no vertex in $(G \backslash A)_{\mid c}$ is won by player $\bar{\alpha}$. Therefore statement (II) holds for $G \backslash A$ and indeed all vertices in $(G \backslash A)_{\mid c}$ are won by player $\alpha$, moreover player $\alpha$ has a strategy $\sigma_{\alpha}$ for $(G \backslash A)_{\mid c}$ that is winning for all vertices. Clearly this strategy can also be applied in game $G_{\mid c}$. Consider valid path $\pi$ in game $G_{\mid c}$ conforming to $\sigma_{\alpha}$. When this path eventually stays in $(V \backslash A)_{\mid c}$ then player $\alpha$ wins because $\sigma_{\alpha}$ is winning here. Otherwise the path visits $A_{\mid c}$ infinitely often, in which case player $\alpha$ can force
the play into $U_{\mid c}$ infinitely often and therefore the highest priority occurring infinitely often has parity $\alpha$. So player $\alpha$ wins all vertices in $V_{\mid c}$ and the algorithm returns winning sets accordingly; statement (II) holds.

Otherwise the algorithm continues with calculating set $B$ (line 17) and $C_{B}$ (line 18).
For the remainder of the proof numerous case distinction need to be made. These distinctions will be presented in a Fitch-like style to improve readability.

First we distinguish two cases for $A_{\mid c}$.
Assume $A_{\mid c}=\emptyset$
Clearly $G_{\mid c}=(G \backslash A)_{\mid c}$, so all vertices in $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ are won by player $\bar{\alpha}$ in game $G_{\mid c}$.
Assume $A_{\mid c} \neq \emptyset$
We use Lemma's 7.7. Lemma 7.3 and induction on $G \backslash A$ to find that the vertices in $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ are won by player $\bar{\alpha}$ in $G_{\mid c}$.
In either case we find that all vertices in $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ are won by player $\bar{\alpha}$ in $G_{\mid c}$.
Assume $c \in C_{B}$
The second subgame that is created by the algorithm (line 19) does not contain any vertices with configuration $c$ because $V_{\| C_{B}}$ is removed from the game. Therefore $W_{0}^{\prime \prime}$ and $W_{1}^{\prime \prime}$ do not contain any vertices with configuration $c$. We find that the only vertices with configuration $c$ that are returned by the algorithm are in the set $B$.
For $c$ to be in $C_{B}$ we must have $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c} \neq \emptyset$. We can apply Lemma 7.7 to find that set $B_{\mid c}$ contains all vertices such that player $\bar{\alpha}$ can force the play to $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ in game $G_{\mid c}$. Earlier we found that all vertices in $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ are won by player $\bar{\alpha}$ in game $G_{\mid c}$, so clearly all vertices in $B_{\mid c}$ are also won by player $\bar{\alpha}$.
The algorithm returns vertices $B_{\mid c}$ to be winning for player $\bar{\alpha}$. Because $c \in C_{B}$ we find that $\bar{\alpha} \in \Delta$ and $\hat{v}_{0} \in B_{\mid c}$. We conclude that statement (I) holds.

Assume $c \notin C_{B}$
If statement (I) holds for $G \backslash A$ then we would have found $\bar{\alpha} \in \Delta$ and $\hat{v}_{0} \in\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$. Because $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c} \subseteq B_{\mid c}$ we would also have found $c \in C_{B}$. Since this is not the case we find that statement (II) holds for $G \backslash A$.
Assume $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}=\emptyset$
In this case $B_{\mid c}=\emptyset$ and the second subgame $G^{\prime}$ created (line 19) projected onto $c$ is identical to $G_{\mid c}$. Using induction we find that statement (I) or (II) hold for $G^{\prime}$. The algorithm returns $W_{0}^{\prime \prime}$ and $W_{1}^{\prime \prime}$ for game $G^{\prime}$ so the same statement that holds for the subgame holds for $G$. Note that $B$ does not contain vertices with configuration $c$.

Assume $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c} \neq \emptyset$
We apply Lemma 7.7 to find that $B_{\mid c}=\bar{\alpha}-\operatorname{Attr}\left(G_{\mid c},\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}\right)$. For the second subgame $G^{\prime}$ created (line 19| we have $\left(G^{\prime}\right)_{\mid c}=G_{\mid c} \backslash B_{\mid c}$ because $V_{\| C_{B}}$ contains no vertices with configuration $c$.
The algorithm returns any vertex $\hat{v}$ in $\left(W_{\beta}^{\prime \prime}\right)_{\mid c}$ to be winning for player $\beta$ in game $G_{\mid c}$. Using induction and Lemma 7.5 we find that indeed $\hat{v}$ is won by player $\beta$ in game $G_{\mid c}$. Furthermore the algorithm returns $B_{\mid c}$ to be winning for player $\bar{\alpha}$. Earlier we found that all vertices in $\left(W_{\bar{\alpha}}^{\prime}\right)_{\mid c}$ are won by player $\bar{\alpha}$ in game $G_{\mid c}$, so clearly all vertices in $B_{\mid c}$ are also won by player $\bar{\alpha}$.
The vertices with configuration $c$ that are returned by the algorithm are in the correct winning set. If statement (I) holds for the subgame $G^{\prime}$ then statement (I) also holds for $G$ because we use $\Delta$ unmodified in the recursion. If statement (II) holds for the subgame $G^{\prime}$ then statement (II) also holds for $G$.

The pseudo code presented for the algorithm uses a set-wise representation of unified parity games. As we have seen previously in the RecursiveUPG algorithm, we can modify the recursive algorithm to use a function-wise representation with a function-wise attractor set calculation. The RecursiveUPGLocal algorithm can be transformed in the same way. The RecursiveUpGLocal algorithm introduces a definition for projecting to sets of configurations as well as the LocalConfs subroutine. We introduce function-wise variants for this definition and subroutine.

Definition 7.4. Given function $X: \hat{V} \rightarrow 2^{\mathfrak{C}}$ we define the projection of $X$ to $C \subseteq \mathfrak{C}$, denoted by $X_{\| C}$, as

$$
X_{\| C}(\hat{v})=X(\hat{v}) \cap C
$$

Algorithm 10 shows a function wise implementation of the LocalConfs subroutine. It is trivial to see that this algorithm and the projection definition are equal under the $=_{\lambda}$ operator to their set-wise counterparts.

```
Algorithm 10 Function-wise LocalConfs subroutine
    function \(\operatorname{FLocalConfs}\left(X: \hat{V} \rightarrow 2^{\mathfrak{C}}\right)\)
        if \(\bar{\alpha} \in \Delta\) then
            return \(X\left(\hat{v}_{0}\right)\)
        else
            return \(\emptyset\)
        end if
    end function
```

We can solve a VPG locally using this local recursive algorithm for unified parity games. We can either represent the parity games set-wise or we can represent them function-wise, in which case we can represent the sets of configurations explicitly or symbolically. In all three cases the time complexities are identical to their global counterparts because in the worst case the vertex we are searching for is never won by player $\bar{\alpha} \in \Delta$ at any recursion level. Furthermore the added projection operation and the LocalConfs subroutine are subsumed in worst-case
time complexity by the attractor set calculation. Therefore the worst-case time complexity argumentation presented for the global variants is also valid for the local variants.

### 7.2.2 Local incremental pre-solve algorithm

The incremental pre-solve algorithm is particularly appropriate for local solving; if we find $v_{0}$ in $P_{\alpha}$ then we know that $v_{0}$ is won by player $\alpha$ for every configuration, therefore we are done for that particular recursion. This can potentially reduce the recursion depth of the algorithm and therefore reduce the number of (pessimistic) games solved.

Furthermore, when there is only a single configuration left the incremental pre-solve algorithm solves the corresponding parity game. When taking a local approach it is sufficient to solve this parity game locally using the local fixed-point iteration algorithm. Note that the pessimistic games still must be solved globally to find as much assistance as possible for further recursions.

If $v_{0}$ is not found in either $P_{0}$ or $P_{1}$ and is only solved when there is one configuration left, then the local algorithm behaves the same as the global algorithm; we have identical worst-case time complexities: $O\left(c * e * n^{d}\right)$.

## 8. Experimental evaluation

The algorithms proposed to solve VPGs collectively all have the same or a worse time complexity than the independent approach. The aim of the collective algorithms is to solve VPGs effectively when there are a lot of commonalities between configurations. A worst-case time complexity analyses does not say much about the performance in case there are many commonalities. In order to evaluate actual running time the algorithms are implemented and a number of test VPGs are created to test the performance on. In this section we discuss the implementation and look at the results.

During the previous sections we put forth a number of hypotheses about the performance of the algorithms introduced. In this section we evaluate these hypotheses, specifically we hypothesised:

- that the recursive algorithm for VPGs can attract a large number of configurations per origin vertex at the same time,
- that the recursive symbolic algorithm for VPGs performs well when solving VPGs originating from FTSs,
- that the incremental pre-solve algorithm outperforms independent approaches and,
- that the increase in performance between a global-collective and local-collective approach is greater than the increase in performance between a global-independent and local-independent approach.

### 8.1 Implementation

The algorithms are implemented in $\mathrm{C}++$ version 14 and use $\mathrm{BuDDy} y^{1} 27$ as a BDD library. The complete source is hosted on github ${ }^{2}$.

The implementation is split in three phases: parsing, solving and solution printing. The solving part contains the implementations of the algorithms presented. The parsing and solution printing parts are implemented trivially and hardly optimized and their running times are not considered in the experimental evaluation.

The parsing phase of the algorithm creates BDDs from the input file and in doing so parts of the BDD cache gets filled. After parsing the BDD cache is cleared to make sure that the work done in the solving phase corresponds with the algorithms presented and no work to assist it has been done prior to this phase. Creating BDDs is not a trivial task, however one could argue that an FTS should already express its transition guards as BDDs. In any case, we leave the creation of BDDs out of scope.

### 8.1.1 Game representation

The graph is represented using adjacency lists for incoming and outgoing edges, furthermore every edge maps to a set of configurations representing the $\theta$ value for the edge. Sets of configurations are either represented symbolically or explicitly. In the former case we use BDDs, in the latter case we use bit-vectors. For independent algorithms the edges are not mapped to sets of configurations. Finally sets of vertices are represented using bit-vectors.

[^0]Note that only the representation of the games used during the algorithm is relevant. Since we do not evaluate the parsing phase it is not relevant how the games are stored in a file.

### 8.1.2 Independent algorithms

Four independent algorithms are implemented, i.e. standard parity game algorithms. A global and local variant is implemented of the following algorithms:

- Zielonka's recursive algorithm and
- fixed-point iteration algorithm.

We implement the fixed-point iteration algorithm to use pre-solved vertices $P_{0}$ and $P_{1}$. When using the algorithm for an independent approach we use $\emptyset$ for $P_{0}$ and $P_{1}$, in which case the algorithm behaves the same as the original fixed-point iteration algorithm.

A few optimizations are applied to the fixed-point iteration algorithm. The following three are described in 4:

- For fixed-point variable $Z_{i}$ its value is only ever used to check if a vertex with priority $i$ is in $Z_{i}$. So instead of storing all vertices in $Z_{i}$ we only have to store the vertices that have priority $i$. We can store all fixed-point variables in a single bit-vector, named $Z$, of size $n$.
- The algorithm only updates a certain range of fixed-point variables. So the diamond and box operations can use the previous result and only reconsider vertices that have an edge to a vertex that has a priority for which its fixed-point variable is updated.
- The algorithm updates variables $Z_{0}$ to $Z_{m}$ and reinitializes $Z_{0}$ to $Z_{m-1}$, however if $Z_{m}$ is a least fixed-point variable then $Z_{m}$ has just increased and due to monotonicity the other least fixed-point formulas, i.e. $Z_{m-2}, Z_{m-4}, \ldots$, will also increase so there is no need to reset them. Similarly for greatest fixed-point variables. So we only to reset half of the variables instead of all of them.

Furthermore, the vertices in the game are reordered such that they are sorted by parity first and by priority second. Using the above optimizations the algorithm needs to reset variables $Z_{m}, Z_{m-2}, \ldots$. These variables are stored in a single bit-vector $Z$. By reordering the variables to be sorted by parity and priority these vertices that need to be reset are always consecutively stored in $Z$. Resetting this sequence can be done by a memory copy instead of iterating all the different vertices. Note that when the algorithm is used by the pre-solve algorithm the variables are not reset to simply $\emptyset$ and $V$ but are reset to two specific bit-vectors that are given by the pre-solve algorithm. These bit-vectors have the same order and resetting can be done by copying a part of them into $Z$.

The advantage of using a memory copy as opposed to iterating all the different vertices is due to the fact that a bit vector uses integers to store its boolean values. A 64-bit integer can store 64 boolean values. Iterating and writing every boolean value individually causes the integer to be written 64 times. However with a memory copy we can simply copy the entire integer value and the integer is only written once.

Finally, priority compression is applied when using the fixed-point iteration algorithm. Priority compression makes sure the lowest priority is 0 or 1 and for every priority $p$ that is lower or equal
to the highest priority occurring in the game we have $p$ being either the lowest priority in the game or there is a vertex in the game with priority $p-1$ [4, 17].

### 8.1.3 Collective algorithms

Six collective algorithms are implemented, i.e. algorithms for solving VPGs. A global and local variant is implemented of the following algorithms:

- Zielonka's recursive algorithm for VPGs with explicit configuration set representation,
- Zielonka's recursive algorithm for VPGs with symbolic configuration set representation and
- incremental pre-solve algorithm.

The incremental pre-solve algorithms uses the fixed-point iteration algorithm as described above to solve the (pessimistic) parity games. When using the incremental pre-solve algorithm we apply priority compression once, directly on the VPG. Since the (pessimistic) parity games that are created during the algorithm have the same vertices as the VPG we do not have to apply priority compression again when using the fixed-point iteration algorithm to solve them.

The incremental pre-solve algorithm creates subgames by splitting the set of configurations. The games we evaluate are based on features so we simply split the set of configurations by arbitrarily choosing a feature and including this feature in one set of configurations and excluding this feature in the other set of configurations. The problem of finding good heuristics to split the sets of configurations is also described in [37. We leave this problem out of scope for this research.

### 8.1.4 Random verification

In order to prevent implementation mistakes 200 VPGs are created randomly, every VPG is projected to all its configurations to get a set of parity games. These parity games are solved using the PGSolver tool [20. All algorithms implemented are used to solve the 200 VPGs independently and collectively, the solutions are verified against the solutions created by the PGSolver.

### 8.2 Test cases

We evaluate the performance of the algorithms on numerous test cases. We have two SPL model checking problems as well as random VPGs. The model checking VPGs are created as described in chapter 5, with the exception that only vertices are added when they are reachable from the initial vertex. So these games are never disjointed. Random games can be disjointed.

In this section we present the different test cases and their characteristics. In the next section the running times are presented.

### 8.2.1 Model checking games

We use two SPL examples. First, the minepump example as described in 25] and implemented in the mCRL2 toolset [6] as described in [37]. The minepump example models the behaviour of
controllers for a pump that pumps water out of a mineshaft. There are 10 different features that change the way the sensors/actors behave. In total there are 128 valid feature assignments, i.e. products.

The mCRL2 implementation creates an LTS with parametrized actions where the parameters describe the boolean formulas guarding the transitions, effectively making it an FTS consisting of 582 states and 1376 transitions. This FTS is interpreted in combination with nine different $\mu$-calculus formulas to create nine VPGs.
We choose to represent the sets of configurations using 10 boolean variables even though 128 configurations could be represented using only 7 boolean variables. By using the same number of variables as there are features the boolean formulas from the FTS are left intact when using them in the VPG. Table 8.1 shows the different formulas, as well as the result of the verification and the size of the resulting games. All the properties can be expressed in the modal $\mu$-calculus we introduced in Definition 3.10. However, for readability, we present them using action formulas, regular formulas and universal quantifiers [22].

Next we have the elevator example, described in 30. This example models the behaviour of an elevator where five different features modify the behaviour of the model. All feature assignments are valid. Therefore, we have $2^{5}=32$ feature assignments, i.e. products. Again an mCRL2 implementation ${ }^{3}$ (created by T.A.C. Willemse) is used to create seven VPGs. The FTS consists of 33738 states and 206290 transitions. Table 8.2 shows the different formulas, as well as the result of the verification and the size of the resulting games.

### 8.2.2 Random games

We create a set of random VPGs such that some games are very similar to the VPGs originating from the SPL verification problems and some games are very different. We use these games to further evaluate the performance of the algorithms.

The guard sets in the minepump and elevator games have a very specific distribution where nearly all of the sets admit either $100 \%$ or $50 \%$ of the configurations. This is because an edge requiring the presence or absence of one specific feature results in a set admitting $50 \%$. On average the edges in the examples admit $92 \%$ of the configurations. Most likely VPGs originating from FTSs will have such a distribution.

Random VPGs can be created by creating a random parity game and creating sets of configurations that guard the edges. For these sets we need to consider two factors: how large are the sets guarding the edges and how are they constructed.

We use $\lambda$ to denote the average relative size of guard sets in a VPG. So for every guard set in a VPG we divide its size by the total number of configurations to get the relative size of the guard set. Taking the average of all these relative sizes calculates $\lambda$.

For every random game we create, we pick a specific $\lambda$. This allows us to create games that have a $\lambda$ similar to those observed in the minepump and elevator example, i.e. $\lambda=0.92$, and games that have a $\lambda$ very different from the SPL games.

Once we decided a value for $\lambda$ we need to decide the sizes of the individual guard set. We do so by using a probabilistic distribution ranging from 0 to 1 with a mean equal to $\lambda$. We consider two distributions, namely a modified Bernoulli distribution which creates guard sets of only relative

Table 8.2: Elevator properties with their partitioning and the size of the resulting VPG. In the $\mathbf{t} / \mathbf{f}$ columns the first number shows for how many products the property holds. Columns $n$ and $d$ shows the number of vertices and distinct priorities in the resulting VPG.
size 0.5 and 1 and a beta distribution which creates guard sets with a more varying range of relative sizes. We can use the former to create random games that are similar to the SPL games and use the latter to create random games that are different to the SPL games.

- A modified Bernoulli distribution; in a Bernoulli distribution there is a probability of $p$ to get an outcome of 1 and a probability of $1-p$ to get an outcome of 0 . We modify this such that there is a probability of $p$ to get 1 and a probability of $1-p$ to get 0.5 . This gives a mean of $1 p+0.5(1-p)=0.5 p+0.5$. So to get a mean of $\lambda$ we choose $p=2 \lambda-1$. Note that we cannot use this distribution when $\lambda<0.5$ because $p$ becomes less than 0 .
- A beta distribution; a beta distribution ranges from 0 to 1 and is curved such that it has a specific mean. The beta distribution has two parameters: $\alpha$ and $\beta$ and a mean of $\frac{\alpha}{\alpha+\beta}$. We pick $\beta=1$ and $\alpha=\frac{\lambda \beta}{1-\lambda}$ to get a mean of $\lambda$.

Figures $8.1,8.2$ and 8.3 show the shapes of the distribution for different values for $\lambda$.

Figure 8.1: Edge guard size distribution for $\lambda=0.5$

(a) Modified Bernoulli distribution with $p=0.5$

Figure 8.2: Edge guard size distribution for $\lambda=0.75$

Figure 8.3: Edge guard size distribution for $\lambda=0.9$

Consider the creation of a random game that has $2^{m}$ configurations, some $\lambda$ is decided upon and one of the above distribution is chosen. For an individual guard set we use the random distribution to decide how large this guard set should be. Consider the creation of a specific guard set and let $r$ denote the relative size of this guard set, decided using the random distribution we chose.

We now need to consider how to create a guard set of relative size $r$. We can simply create a random set of configurations without any notion of features; we call this a configuration based approach. Using this approach we can easily create a guard set of relative size $r$ by simply picking $\left\lfloor 2^{m} * r\right\rfloor$ configurations randomly.

Alternatively we can use a feature based approach where we create sets by looking at features. Consider features $f_{0}, \ldots, f_{m}$, we can create a boolean function that is the conjunction of $k$ features where every feature in the conjunction has probability $\frac{1}{2}$ of being negated. For example when using $k=3$ and $m=5$ we might get boolean formula $f_{1} \wedge \neg f_{2} \wedge \neg f_{4}$. Such a boolean formula corresponds to a set of configurations of size $2^{m-k}$ and a relative size $\frac{2^{m-k}}{2^{m}}=2^{-k}$. Since we are creating a set of relative size $r$, we choose $k=\min \left(m,\left\lfloor-\log _{2} r\right\rfloor\right)$. When using a feature based approach we can only create sets that have a relative size of $2^{-i}$ for some $i \in \mathbb{N}$.

When creating a random game for some $\lambda$ we have considered how we can choose the size of individual set sizes and how to construct sets of that size. This gives us four different ways to construct games:

1. Bernoulli distributed and feature based. These games are most similar to the SPL games.
2. Bernoulli distributed and configuration based. These games do have the characteristics of an SPL game in terms of set size but have unstructured sets guarding the edges. Furthermore with a configuration based approach fewer guard sets will be identical than with a feature based approach.
3. Beta distributed and configuration based. These games are most different from the SPL games.
4. Beta distributed and feature based. Using a feature based approach we can only create sets of size $2^{-i}$ for any $\lambda \geq \frac{1}{2}$. So using a beta distribution we must round to such a size. Almost all the sets will get a relative size of either $\frac{1}{2}$ or 1 . So this creates almost the exact same games as using the Bernoulli distribution, therefore we will not consider this category of games.

| Category | \# vertices | Maximum \# successors | \# distinct priorities | \# confs | $\lambda$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Type 1, scale in $\lambda$ | $100-600$ | $3-20$ | $1-10$ | $2^{4}-2^{12}$ | $\frac{\text { game } n r}{100}$ |
| Type 2, scale in $\lambda$ |  |  |  |  |  |
| Type 3, scale in $\lambda$ |  |  |  |  |  |
| Type 1, scale in \# confs | 100-600 | $3-20$ | 1-10 | $2^{\text {game } n r}$ | 0.92 |

Table 8.3: Categories of random games

We create four sets of random games. For random games of type 1,2 and 3 we create 25 games: game 75 to game 99, where game $i$ has $\lambda=\frac{i}{100}$ and a random number of features, nodes, edges and maximum priority. Furthermore we create 52 games to evaluate how the algorithm scales when the number of features becomes larger. For every $i \in[2,15]$ we create random games $i$, $i .25, i .50$ and $i .75$ of type 1 with $\lambda=0.92,\lfloor i\rfloor$ features and a random number of nodes, edges and maximum priority.

Besides the number of configurations and the value for $\lambda$ we need to choose the number of vertices for a game, the minimum number of successors of a vertex, the maximum number of successors of a vertex and the number of distinct priorities in the game. The number of minimum and maximum successor is decided per game. So if we pick $l$ and $h$ as the number of minimum and maximum then for every vertex in the game we uniformly pick its number of successors between $l$ and $h$.

Table 8.3 shows the different categories of games and the corresponding parameters. The minimum number of successors per vertex is always 1 so this value is omitted from the table. The games that scale in $\lambda$ share the same random configuration per game number. So game $i$ of type 1 that scales in $\lambda$ has the same number of vertices, maximum successors, distinct priorities and configurations as game $i$ of type 2 and 3 that scale in $\lambda$.

### 8.3 Results

In this section the experimental results are presented ${ }_{4}^{4}$ We evaluate the performance on six sets of games:

- the minepump games,
- the elevator games,
- random games of type 1 with an increasing $\lambda$,
- random games of type 2 with an increasing $\lambda$,
- random games of type 3 with an increasing $\lambda$, and
- random games of type 1 with an increasing number of configuration.

We present the times it took to solve a VPG. For an independent approach this means the sum of the times it takes to solve every projection of the VPG. For a collective approach this

[^2]simply means the solve time for the VPG. In either case we only measure the solve time; parsing, projecting and solution printing is excluded from the evaluation.

The exact times can be found in appendix $A$ in this section the results are visualized and presented in a way such that we can easily compare independent and collective approaches. We have four independent approaches:

- Recursive algorithm (global),
- Recursive algorithm (local),
- fixed-point iteration (global) and
- fixed-point iteration (local).

For every set of problems we present four charts; for every independent approaches we present a chart where its performance is compared to one or two collective algorithms. We compare the performance of the recursive algorithm for VPGs with the performance of the original recursive algorithm and the performance of the incremental pre-solve algorithm with the performance of the fixed-point iteration algorithm. In some of the charts the solve times are divided by the independent solve times to visualize how much better or worse the collective variants perform.

The following legend holds for all charts presented in this section:

Independent approaches:
_Recursive algorithm for parity games (global)
_— Fixed-point iteration algorithm for parity games (global)
=- = = = Recursive algorithm for parity games (local)

- =-=- Fixed-point iteration algorithm for parity games (local)

Collective approaches:
__ Recursive algorithm for VPGs with a symbolic representation of configurations (global)
_ Recursive algorithm for VPGs with an explicit representation of configurations (global)
_Incremental pre-solve algorithm (global)
" $=\mathrm{=}=\mathrm{=}$ = Recursive algorithm for VPGs with a symbolic representation of configurations (local)
=-=-= Recursive algorithm for VPGs with an explicit representation of configurations (local)
= = = = = Incremental pre-solve algorithm (local)
All the experiments are ran on a Linux x64 operating system with an Intel i5-4570@3.20 GHz processor and 8GB of DDR3 RAM.

### 8.3.1 SPL examples

Figures 8.4 and 8.5 show the solving times (in ms) of the algorithms when applied to the SPL examples.

Figure 8.4: Running times on the minepump games. The x-axis shows the game numbers, these correspond with the formulas described in Table 8.1. The $y$-axis shows, on a logarithmic scale, the number of milliseconds required to solve the VPG.

For the minepump example we see that the recursive algorithm for VPGs using a symbolic representation performs particularly well; about a 3 to 18 times increase in performance compared to the independent approach. For the elevator example we also find an increase in performance for the symbolic recursive algorithm compared to the independent algorithm; about a 2 to 6 times increase. The difference is most likely because the minepump games have twice as many features as the elevator games have. Notably, for the elevator games we also find a good performance for the incremental pre-solve algorithm, which we do not find for the minepump games. Finally, we observe that there is no clear difference between the relative performances of the global algorithms and the local algorithms.

Figure 8.5: Running times on the elevator games. The x-axis shows the game numbers, these correspond with the formulas described in Table 8.2. The y-axis shows, on a logarithmic scale, the number of milliseconds required to solve the VPG.

### 8.3.2 Random games

Figure 8.6 shows the performance of the algorithms on type 1 games. The recursive algorithms for VPGs perform quite well, even though there are a few instances where the performance is worse than the independent approach. The symbolic variant performs quite a bit better than the explicit variant. The relative performance of the local variants of the recursive algorithms is about the same as the relative performance of the global variants.

For the incremental pre-solve algorithm we do see a big difference between a local and global approach. The global variant performs well only for games 90 and up. The local variant, however, performs well for nearly all the games. Furthermore, even for the games where the global variant performs well relative to the independent global approach does the local variant performs even better relative to the independent local approach.

Figure 8.6: Running times on random games of type 1 with $\lambda=\frac{\text { game } n r}{100}$. The x -axis shows the game numbers. The y-axis shows, on a logarithmic scale, how much faster the algorithms solved a VPG compared to the independent algorithm. Clearly the independent algorithm always has value of 1 for every VPG. If an algorithm has a value above 1 for a VPG then it performed worse than the independent algorithm; if the value is below 1 then it performed better than the independent algorithm.

Figure 8.7 shows the performance of the algorithms on type 2 games. For the recursive algorithms we see that the explicit variant takes over from the symbolic variant. This is to be expected since these games have edge guards that are not created from features but created by picking random configurations. This decreases the performance of symbolic set operations but has no effect the performance of explicit set operations. Both variants still perform somewhat better than the independent approach. Again we do not find a significant difference between the global and local approach.

For the incremental pre-solve algorithm we find a similar result as with type 1 games. The global variant performs well only when $\lambda$ is high. The local variant performs significantly better and performs well for almost all games.

Figure 8.7: Running times on random games of type 2 with $\lambda=\frac{g a m e ~ n r}{100}$ The x -axis shows the game numbers. The y-axis shows, on a logarithmic scale, how much faster the algorithms solved a VPG compared to the independent algorithm.

Figure 8.8 shows the performance of the algorithms on type 3 games. For these games we see the symbolic variant of the recursive algorithm performing worse than the independent approach for almost all games. The explicit variant still performs significantly better than the symbolic variant and performs somewhat better than the independent approach. This is similar to type 2 games, which is to be expected because both types of games use configuration sets not based on features. Again we do not find a significant difference between the global and local approach.

The global incremental pre-solve algorithm performs worse than the independent approach for almost all games. Notably for these games we do not find a significant increase in relative performance when using a local variant.
Notably, the explicit recursive algorithm seems to be the only algorithm unaffected by the fact that the guard sets sizes of type 3 games vary wildly (they are distributed using a beta distribution). Maybe surprisingly, the incremental pre-solve algorithm is affected heavily by this. This is most likely because there are a lot fewer edges that admit all configurations and therefore player $\alpha$ will probably win fewer vertices in a pessimistic game for player $\alpha$.

Figure 8.8: Running times on random games of type 3 with $\lambda=\frac{\text { game } n r}{100}$ The x -axis shows the game numbers. The $y$-axis shows, on a logarithmic scale, how much faster the algorithms solved a VPG compared to the independent algorithm.

### 8.3.3 Scaling

Figure 8.9 shows the performance of the algorithms on type 1 games where the number of configurations increase exponentially in the x-axis of the charts. For the recursive algorithm we see that the collective approach starts outperforming the independent approach around $2^{4}$ configurations. As the number of configurations grow we see that the symbolic variant keeps increasing in relative performance while the explicit variants relative performance starts to flatten. This is to be expected because the performance of the explicit variant always scales linearly in the number of configurations. In the worst case the symbolic variant scales quadratically in the number of configurations, however when the sets of configurations can be represented efficiently it scales much better and in this case sublinear (since the performance of the local variant keeps increasing relative to the explicit variant).

The global incremental pre-solve algorithms does not increase notably in relative performance when the number of configurations increases. However, the relative performance of the local variant does increase in performance when the number of configurations increases. The recursion of the incremental pre-solve algorithm can be conceptualized as a tree where at every node the
algorithm tries to increase the pre-solved vertices. The local variant can terminate when at some node the vertex that is being locally solved is found. In such a case the whole subtree of that node is longer computed. When the number of configurations grow then potentially the size of this subtree also grows. The fact that the local incremental pre-solve algorithm scales well in the number of configurations is most likely because the algorithm can terminate early for a relatively large set of configurations.

Figure 8.9: Running times on random games of type 1 with $\lambda=0.92$ and the number of features equal to $\lfloor$ game $n r\rfloor$. The x -axis shows the game numbers. The y -axis shows, on a logarithmic scale, how much faster the algorithms solved a VPG compared to the independent algorithm.

### 8.3.4 Internal metrics

Earlier we hypothesised that the recursive algorithm for VPGs could perform well if we can attract many configurations simultaneously. For every VPG we measure the average number of configurations that were attracted simultaneously. We measure this relative to the total number of configurations in the VPG. This gives a number for every VPG. For every set of VPGs we average this number to get an average set size for every problem set. These values indicate how many configurations were attracted simultaneously. In Table 8.4 these values are presented for the different problems being globally solved, note that whether the sets are represented explicitly or symbolically is irrelevant. We see that this number somewhat predicts the performance of the
recursive algorithms.

| Minepump | $46 \%$ |
| :--- | :--- |
| Elevator | $51 \%$ |
| Type 1, scaling in $\lambda$ | $61 \%$ |
| Type 2, scaling in $\lambda$ | $55 \%$ |
| Type 3, scaling in $\lambda$ | $22 \%$ |
| Type 1, scaling in \# confs | $72 \%$ |

Table 8.4: Relative size of attracted sets
The incremental pre-solve algorithm tries to outperform its independent counterpart by growing the set of pre-solved vertices. We measure how many vertices are pre-solved for the different sets of problems. For every VPG we measure the average number of pre-solved vertices for every (pessimistic) parity game solved. We measure this relative to the number of vertices in the VPG. This gives a number for every VPG. For every set of VPGs we average this number to get an average vertex size for every problem set. These values indicate how many vertices were pre-solved on average. In Table 8.5 these values are presented for the different problems. The algorithm recurses into two branches after every two pessimistic parity games solved. The further we go down the tree the higher the number of pre-solved vertices. So the average numbers presented in the table are quite high because there are exponentially more parity games that are further down the recursion tree.

For the global variant the number presented in Table 8.5 somewhat predicts the performance of the incremental pre-solve algorithm compared to the fixed-point iteration algorithm. For the local variant this is not the case. The local variant performs well when parts of the recursion tree are not calculated because we have terminated early. However, if the recursion tree is less deep then the numbers in the table decrease. Therefore, for the local algorithm the numbers do not predict the performance.

|  | Global | Local |
| :--- | :--- | :--- |
| Minepump | $58 \%$ | $29 \%$ |
| Elevator | $84 \%$ | $38 \%$ |
| Type 1, scaling in $\lambda$ | $87 \%$ | $9 \%$ |
| Type 2, scaling in $\lambda$ | $82 \%$ | $9 \%$ |
| Type 3, scaling in $\lambda$ | $57 \%$ | $19 \%$ |
| Type 1, scaling in \# confs | $91 \%$ | $12 \%$ |

Table 8.5: Relative number of pre-solved vertices

### 8.3.5 Discussion

From the experimental results we observe that the symbolic variant of the recursive algorithms for VPGs performs well for the model verification problems. For type 1 random games it also performs well and particularly scales very well in the number of configurations. For type 2 and 3 games the sets of configurations can no longer be efficiently represented symbolically and performance drops.

After comparing independent and collective approaches we compare the performances of the algorithms overall.

First we compare the independent algorithms. Table 8.6 shows for every set of VPGs how long it took each algorithm to solve all the VPGs in that set. We observe that the recursive algorithm

|  | Recursive <br> global | Recursive <br> local | Fixed-point <br> global | Fixed-point <br> local |
| :--- | :--- | :--- | :--- | :--- |
| Minepump | 1032 ms | 788 ms | 16713 ms | 15989 ms |
| Elevator | 79468 ms | 65588 ms | 7393468 ms | 2108539 ms |
| Type 1, scaling in $\lambda$ | 1830 ms | 1730 ms | 53677 ms | 51506 ms |
| Type 2, scaling in $\lambda$ | 1936 ms | 1721 ms | 74710 ms | 72536 ms |
| Type 3, scaling in $\lambda$ | 1892 ms | 1680 ms | 62568 ms | 51231 ms |
| Type 1, scaling in \# confs | 32903 ms | 29393 ms | 439199 ms | 274201 ms |

Table 8.6: Comparison of independent algorithms. The times shown are the times it took an algorithm to solve all the VPGs in a problem set independently.
performs significantly better than the fixed-point algorithm across all problems. We also see that the local variants perform somewhat better across the board. In table 8.7 we compare the performance of the collective algorithms. We observe that the recursive symbolic variant performs the best for model-checking problems and for type 1 games. Furthermore, most likely the algorithm will scale well for models with a large number of features. The local variant of the incremental pre-solve algorithm also performs well relative to its independent counterpart. However, because the fixed-point iteration is heavily outperformed by the recursive algorithm its overall performance is worse that the recursive variants. On average, the global variant of the incremental pre-solve algorithm also outperforms its independent counterpart. However, we have seen in the comparison charts that it does so less consistently and significantly than the local variant and the symbolic recursive algorithm do.

|  | Recursive <br> explicit <br> global | Recursive <br> explicit <br> local | Recursive <br> symbolic <br> global | Recursive <br> symbolic <br> local | Incremental <br> pre-solve <br> global | Incremental <br> pre-solve <br> local |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Minepump | 1019 ms | 942 ms | 148 ms | 133 ms | 5900 ms | 3223 ms |
| Elevator | 81225 ms | 78635 ms | 25764 ms | 25602 ms | 1634659 ms | 1278387 ms |

| Type 2, <br> scaling in $\lambda$ | 234 ms | 199 ms | 2741 ms | 2585 ms | 67458 ms | 13459 ms |
| Type 3, <br> scaling in $\lambda$ | 677 ms | 665 ms | 15891 ms | 15897 ms | 196328 ms | 102182 ms |
| Type 1, <br> scaling <br> in \# confs | 1088 ms | 1048 ms | 114 ms | 104 ms | 53460 ms | 683 ms |

Table 8.7: Comparison of collective algorithms. The times shown are the times it took an algorithm to solve all the VPGs in a problem set collectively.

Furthermore, we observe that the explicit variant of the recursive algorithm performs decent across most games. We conclude from this that the efficiency of the symbolic algorithm does not only come from representing sets of configurations efficiently; using a collective approach even without this representation seems to be efficient. It seems that, for the games we experimented with, using the explicit recursive algorithm never significantly hurts performance but in some
cases can significantly increase performance compared to the independent approach.
Earlier we hypothesized that a local-collective approach would increase performance more compared to a global-collective approach than a local-independent approach would compared to a global-independent approach. We observe that this is the case for the incremental pre-solve algorithm but not at all the case for the recursive algorithms. Furthermore, this is only the case for the random games; in the SPL games there is not a significant difference in relative performance. We conclude that local solving has the potential to increase performance, however this is not a given and depends on the algorithm and the type of VPG.

## 9. Conclusion

An SPL can be verified using traditional model-checking techniques. These techniques check every product described by the SPL independently. However, the number of products potentially scales exponentially in the number of features. So we could end up with a large number of products which makes independent checking undesirable. We have presented a method of modelchecking an SPL, that models its behaviour using an FTS, such that commonalities between the different products are exploited to increase performance.

We generalized parity games to express variability; these games are called variability parity games (VPGs). VPGs express variability through configurations; a VPG describes a parity game for every configuration. We have shown that we can construct a VPG from an FTS and modal $\mu$-calculus formula such that solving the FTS gives the information needed to decide which products satisfy the formula. VPGs can be solved independently where we solve every parity game described by the VPG separately. We introduced several collective algorithms that solve a VPG as a whole and try to exploit commonalities between the different configurations.

First we introduced a variant of Zielonka's recursive algorithm that solves VPGs. The algorithm views a VPG as a collection of parity games; a parity game for every configuration. We can represent such a collection with a single game graph and for every vertex and edge we have a set of configurations indicating if this vertex or edge is part of the parity game of that configuration. We modified the recursive algorithm to use such a representation. Specifically, we modified the attractor algorithm to try and attract multiple configurations per vertex at the same time. This modified attractor algorithm relies heavily on set operations over the sets of configurations associated with the vertices and edges. These sets can be either represented symbolically or explicitly, giving two variants of the recursive algorithm for VPGs.
Next we introduced the incremental pre-solve algorithm for VPGs. This algorithm tries to find vertices that are won by one of the players for all configurations, if such a vertex is found it is said to be pre-solved. The algorithm tries to find these vertices and then splits the configurations in two sets and goes into recursion for both of them. In the recursion the configuration set has decreased in size so potentially more vertices can be pre-solved. The algorithm finds these vertices through solving pessimistic parity games. Pessimistic parity games are created from a VPG and for a player $\alpha$, they have the property that any vertex won by player $\alpha$ is also won by player $\alpha$ in the VPG played for any configuration. The incremental pre-solve algorithm creates two pessimistic parity games (for player 0 and 1 ) and solves them using the fixed-point iteration algorithm. The fixed-point algorithm is modified to use vertices that already were presolved to increase its performance. The algorithm incrementally builds up the set of pre-solved vertices until either all vertices are pre-solved or a single configuration remains. In the worst case the algorithm solves linearly more (pessimistic) parity game than using an independent approach would. However, by increasing the number of pre-solved vertices the algorithm tries to outperform the independent approach by solving the (pessimistic) parity games increasingly quicker.

We introduced local variants of the recursive algorithm for parity games and the fixed-point algorithm for parity games. A local parity game algorithm tries to only determine the winner of a single vertex instead of all the vertices, potentially increasing its performance. We also introduced local variants of the collective algorithms mentioned above.

The incremental pre-solve algorithm has the same time complexity as independently solving a VPG using the fixed-point iteration algorithm. The recursive algorithms for VPGs have a worse worst-case time complexity than independently solving a VPG using the recursive algorithm for parity games. However, the aim of the algorithms is to solve VPGs originating from FTSs
efficiently. Often times these VPGs will have a lot of commonalities between the configurations. The algorithms are implemented and their actual performance is compared to independent approaches. The minepump and elevator SPLs are used to evaluate the performances. Furthermore a collection of random games is created with different characteristics ranging from very similar to VPGs originating from SPLs to completely different from VPGs originating from SPLs.

We observed that for the SPL VPGs and random VPGs created to be similar to SPL VPGs the symbolic variant of the incremental pre-solve algorithm performs best. The incremental pre-solve algorithm generally also outperforms its independent counterpart, i.e. independently solving a VPG using the fixed-point iteration algorithm. However, for the SPL VPGs, it does so less significantly and consistently than the symbolic recursive algorithm does. It also scales poorer in the number of features than the symbolic recursive algorithm does. Furthermore the independent approach using the recursive algorithm greatly outperforms the independent approach using the fixed-point algorithm. Because the incremental pre-solve algorithm uses the fixed-point algorithm its absolute performance is significantly worse than the recursive algorithm for VPGs.

We observed the explicit recursive variant performs either very similar or better than the independent approach across all games considered. From this we conclude that, even when VPGs are less similar to the SPL VPGs, there is room to exploit commonalities and in some cases increase performance without running the risk of significantly decreasing performance. Whether there are types of VPGs for which the explicit algorithm would perform significantly worse than the independent approach is left unanswered.

Notably, the difference between the local and global variants of the recursive algorithms for VPGs is very little. However, the difference between the local and global variant of the incremental pre-solve algorithm is large for some of the games. However, the difference is not large for the SPL VPGs. We conclude that local algorithms for VPGs can increase performance compared to global algorithms, more so that locally solving parity games increases performance compared to globally solving parity games. However, this is highly dependent on the algorithm and the type of VPG.

Future work Even though the incremental pre-solve algorithms performance was not the best, it did on average outperform its independent counterpart. Therefore it would be interesting to study the incremental pre-solve algorithm using a different way of solving pessimistic parity games; for example, using a variant of the recursive algorithm that can work with pre-solved vertices. This would potentially yield an algorithm that is more robust than the symbolic recursive algorithm in the sense that it performs well across different VPGs and not only for VPGs that originate from SPLs.

In this research we did not look into ways of splitting configurations in such a way that the incremental pre-solve algorithm performs well; we simply split configurations based on an arbitrary feature. In [37] it is observed that finding good heuristics for splitting sets of products is relevant to efficiently verifying SPLs. It would be interesting to study such heuristics and to evaluate if heuristics found for VPGs would applicable to the method described in 37, and vice versa.

Furthermore, many optimizations are known for solving parity games 39, 19, 21, 42]. It would be interesting to study if these improvements are applicable to VPGs and if they increase the performance of VPG solving more than they increase the performance of parity game solving.

Finally, the creation of VPGs is left unstudied in this thesis, it would be interesting to study how one could efficiently create VPGs from FTSs including the creation of BDDs.
